Chancre of the Upper Gum.—Extragenital syphilis is a subject that would seem to have been sufficiently exploited by this time, still there occur cases which are of such importance not only medically, but also sociologically, that every new contribution to this subject must be welcomed by the profession. A case not only instructive, but highly interesting because of its rarity, is reported by M. A. Chlenoff (Prak. Vrach, No. 35, 1903) in a peasant woman twenty-nine years of age, who was admitted to the hospital with an eruption on the body of three days' duration, and pain in the upper gum of two weeks' duration. Patient claims to have been affected from one of her lovers who suffered from syphilis, by using his towels, tooth-brush, etc. The pain in the gum was accompanied by unpleasant sensation, but no tenderness on either eating or drinking. Examination elicited a large swelling that invaded the alveolar processes of a dark, cherry-red color, with prominent vessels on its surface, but without any erosion anywhere around it. Submaxillary glands markedly enlarged, and to an extent the sublingual. The cervical and axillary glands but little affected. The body is covered thickly by syphilitic papules, especially the trunk. The patient was given hypodermic injections of a two-per-cent. solution of hermophenol every other day, and local applications of tincture iodine with glycerin and potassium iodide. After 20 injections the patient left the hospital with the eruption somewhat atrophied, and the chancre considerably paler and absorbed. Patient continued an outdoor treatment of another 8 injections, and subsequently 16 inunctions of 2.0 of mercurial ointment. She entirely recovered, but was readmitted in a couple of months with syphilitic ulcer of the arms; pronounced leucoderma colli, while the former chancre disappeared entirely, leaving but two small cicatrices. While the diagnosis of the case leaves no doubt as to the nature of the affection, the clinical picture of the chancre presents some interesting points. According to Fournier there are two clinical types of this chancre. The first presents the usual phenomena of chancre and is distinguished only by its small size and a semilunar shape embracing two or rather three neighboring teeth; it presents either an erosion or a superficial wound, distinctly limited, smooth, even and of a dark-red color. In the other type of the chancre of the gum the erosion is not limited by a distinct, prominent border, and its bottom is rather uneven, and of a variety of colors; it is also accompanied by symptoms of an adjacent periostitis, and subjective symptoms such as local tenderness, pain, pain on touching, as well as in eating and drinking, etc. In a general way it may be said that the diagnosis of this condition is sometimes difficult and becomes clear only because of the presence of other symptoms, and especially the characteristic adenopathy. The author refers his case rather to the second class, for it resembles this type more than the other. As etiological factors various authors mention the following: Tooth-brushes, operations on the teeth and mouth, musical instruments, cigarettes, mouthfeeding, unnatural coitus per os, etc.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Changes in Spinal Ganglia after Division of Peripheral Nerve and Posterior Root.—With division of the peripheral nerves K. Kleist (Virchow's Archiv, Vol. 173, No. 3) found signs of cell-degeneration in the spinal ganglia, reaching their highest degrees during the first month and then slowly disappearing until the end of the fourth month. The lesions involve chiefly the "tigroid" substance or substance stained according to Nissl, the nucleus and the ground-substance. The tigroid substance appears as finely granular or coarse and polyhedræ or spindle-shaped masses, while the nucleus will occupy an eccentric position. After severance of the posterior root the same changes are observed, but not to such a degree. The varying appearance of the tigroid substance is most likely due to a difference in cell-structure, which probably goes hand in hand with variations in physiological function. The end stages are always complete degeneration and atrophy.

Esophageal Diverticula.—In a comprehensive article G. Riebold (Virchow's Archiv, Vol. 173, No. 3) states that traction diverticula are very frequent in adults (3.5 per cent. of all autopsies on adults and none in children under fifteen years). Their location is usually the anterior or lateral (more often the right than the left) wall at the level of the bifurcation; in four cases they were seated 5 to 6 cm. (2½ inches) higher, in one case 10 cm. (5 inches) lower, and in another the posterior wall was involved. In the majority of cases only one is found, but at one autopsy there were as many as nine. They all stand in intimate relation with indurated chalicotic or anthracotic lymphnodes. The form most frequently encountered is that of a funnel 3 to 6 mm. (1/10 to 1/5 inches) deep, but a large number of variations may be described. The shape of the opening is not constant and the longest diameter is usually directed obliquely upward. All the layers of the esophagus may participate, but usually the mucous membrane is defective. The clinical importance of these diverticula lies in the possibility of perforation and infection of the surrounding tissues. The stagnating food may set up an inflammation and progressive ulceration or else the gland will suppurate and discharge into the esophagus. The result is an enlargement of the original diverticulum or a purulent mediastinitis or perforation of the pus into trachea, bronchi, lung, pleura, pericardium or vessels. Carcinoma or tuberculosis are very apt to develop upon the scar tissue of an old diverticulum. The diagnosis during life has never been made. The fact that a glandular inflammation is apt to spread toward the esophagus and draw out its walls is best explained by an obstruction of lymph-channels which permits a retrograde transport of germs. Similar diverticula of the trachea and bronchi have also been described, but here the cartilaginous rings offer a much greater resistance than the soft walls of the esophagus. In the second group, the diverticula by traction and pressure, part of the wall of a traction diverticulum is bulged out or else the entire pouch has yielded and it would be hard to distinguish it from a pressure diverticulum were it not for the remains of glands and chronic inflammation in the neighborhood, and perhaps the deposit of coal in the walls. This group is rare and position and etiology are the same as in the preceding group. Lastly, the pure pressure diverticula claim attention especially

since their causation has been a mooted point. It is probable that the pressure of a morsel passing down the esophagus or forced expiratory acts bulge out a posterior pharyngeal wall weakened congenitally or by trauma. The muscle fibers of the inferior constrictor will yield so that a hernia of the mucous membrane can readily take place. After the bag has attained a certain size the pressure of the contained food will enlarge it more and more. The diagnosis is fairly certain and treatment is also satisfactory; formerly one-fourth of the cases died of starvation or aspiration pneumonia, with pulmonary gangrene, but now a large number are amenable to operation. Lower down in the esophagus, especially on its anterior and lateral wall, above physiological stenoses, similar pathological lesions are sometimes seen, and it is likely that here also a congenital weakness is at fault.

Necrobiotic Changes of Blood.—By keeping freshly-drawn human blood in hermetically-sealed capillaries up to one hundred days, K. Bodon (Virchow's Archiv, Vol. 173, No. 3) could study the resistance of the various cells and the change which they undergo with time. It appears that the large unicellular elements of Ehrlich and the transitional forms disappear first; then follow the large lymphocytes and the multinuclear leucocyte. The neutrophiles seem to be more resistant than the acidophiles. Last of all the small lymphocytes and the red cells are destroyed. The red cells become smaller and thinner, their protoplasm splits up and umbilication disappears, and in the oldest tubes there is complete disintegration. With stains there is polychromatophilia, hypo- up to complete achromatosis. The appearance of granules within the protoplasm, described in lead poisoning and other diseases, does not seem to be a necrobiotic phenomenon. The leucocytes undergo plasmolysis, the granules are irregularly distributed within the cell-body and show hypo- and metachromatosis, and finally the protoplasm breaks up completely. Eccentric position of the nucleus with change of contour, disappearance of nuclear network, pyknosis, perichromatosis are also observed. On the whole the nuclei and the specific granules resist destruction longer than the protoplasm.

Splenic Leucemia in a Calf.—An interesting observation is recorded by D. A. DeJong (Virchow's Archiv, Vol. 173, No. 3), who noticed all the lesions of splenic leucemia in a calf five weeks old. The organs were icteric, the spleen as large as in an adult animal, and the blood showed an increase in large uninuclear elements with microcytosis. Since neither lymph-nodes nor bone-marrow gave evidence of any pathological lesion the case must be looked upon as a purely splenic type. The jaundice could only be explained by an increased destruction of red cells in the blood current, since no obstruction in the biliary passages was present. In all probability the leucemia was congenital.

Suprarenals in Congenital Syphilis.—The suprarenal bodies do not frequently show pathological lesions in congenital syphilis, but occasionally gummata are found both in children and in adults. N. Gulecke (Virchow's Archiv, Vol. 173, No. 3) has discovered a new lesion which seems to be characteristic for syphilis. Corresponding to macroscopically visible, yellow, cheesy foci he found irregularly distributed throughout the cortex small and large areas with necrotic cells. Their usual seat is the outer portion of the zona fasciculata and the zona glomerulosa, and their shape suggests an infarct. In the center the shape and arrangement of the cells can still be discerned while the periphery is sharply demarcated from healthy tissue, and is surrounded by a zone of leucocytes. Fat, lime and pigment are deposited, but cheesy degeneration is absent. In other parts of the cortex there were small accumulations of round cells, and increase in connective tissue, and a slight degree of periarteritis. These lesions were not found in 15 non-syphilitic cases examined, while in 7 syphilitic necrotic foci were present in 3. They are not due to arterial changes, but probably represent a direct destruction of the parenchyma by the syphilitic virus, yet not absolutely specific for syphilis.

Multiple Myelomata.—According to the description of S. Saltykow (Virchow's Archiv, Vol. 173, No. 3), multiple myelomata consist of round cells which closely imitate normal marrow cells and which are arranged into irregularly shaped fields by means of narrow bundles of connective tissue. When the cells are closely applied to each other they may have an angular form. The nuclei may be small and dark without distinct structure or large and pale, with nucleoli and chromatin granules. The nucleus generally makes up the greater part of the cell body, but in other places the cells closely simulate flat epithelial elements. Eosinophile granules may be present in abundance. Some nodules consist almost entirely of blood-spaces lacking an endothelial lining, and filled more or less with tumor-cells; this explains the occasional presence of a large number of colorless elements in the blood. The marrow in the immediate neighborhood of the tumor has a similar structure with many giant and fat cells, but generally lacking the wide blood-channels. In other organs, especially in the liver, there may be accumulations of myelocytes. Macroscopically the tumors in the bone possess a distinctly red color due to their vascularity and to hemorrhages, except in the more peripheral portions. Bone is absent, except on the inner surface of the periosteum, which is continued unchanged over the tumor.

Rupture of Gall-bladder after Carcinoma.—B. Huguenin (Virchow's Archiv, Vol. 173, No. 3), performing an autopsy on a man fifty-eight years old, discovered a papilliferous carcinoma, rich in dilated blood-vessels at the junction of the cystic and hepatic ducts. The immediate results were a retention of bile with interstitial biliary hepatitis, dilatation of the biliary passages with moderate new formation of the smallest canals and papillary proliferation of their epithelial cells. The cholemia resulted in hemorrhages all over the body; the most severe bleeding took place from the vascular tumor itself and led to rupture of the gall-bladder, inundation of the entire peritoneal cavity and death. The numerous necroses in liver and pancreas were probably due to some toxin circulating in the blood. In the pancreas they were converted into small cysts, probably owing to autodigestion.

EYE, EAR, NOSE AND THROAT.

A Cause and Cure of Hay Fever.—It is generally admitted now that there are at least two factors of causation in every case of hay fever, the neurotic condition of the nervous system and the exciting cause. Besides these some derangement of the mucous membrane of upper air passages is found in many instances. F. E. Stowell (N. Y. Med. Jour., Sept. 5, 1903) being a victim of this disease himself, and acting upon the belief that it was a disease of the nervous system and not due to some irritant deposited upon the nasal mucosa began to search for some factor which was present at this time of the year and absent at other times. He hit upon the possibility of an influence from the strongly actinic rays of the sun at this season affecting the very sensitive ciliary nerves and reflexly causing the paroxysms of an attack of hay fever. Acting upon this

mode of reasoning he began to wear colored glasses and found that he was almost immediately relieved. The condition at once returned if he went out without wearing them. He has since improved two or three other cases but is anxious to have the simple experiment tried by others to determine what percentage of cases can be helped in this way.

Rational Treatment for Mouth-breathing.—Diseases of the upper air passages are so common in this part of the country that the climate is held responsible by many as being the chief factor of causation. To be sure a severe climate must necessarily greatly affect mucous membranes which are easily influenced by rapid changes but the improper use of our respiratory apparatus is urged by W. H. Fitzgerald (Med. Rec., Sept. 5, 1903) to be fully as potent a factor as the severity of the climate. So many people are either confirmed or moderate mouth-breathers and all these must necessarily have more or less constant nasopharyngeal catarrh. Many people are not conscious that they breathe other than through the normal passages and will not admit it until you convince them by engaging them in conversation or have them read for you when they will be surprised to learn that they have spoken several sentences or read several paragraphs without once closing their mouths. They are the ones who after lecturing or reading aloud, or perhaps singing, are dry of mouth or husky of speech. Douches are usually harmful in such cases. The nose needs more air not more water. Of course the only rational means of curing such a condition is by removing all growths and deformities which encroach upon the normal passages. This done, the cases of habit mouth-breathing demand care and attention. The nose must be exercised. The patient is ordered to breathe forcibly through his nostrils at the rate of one inspiration per second for ten seconds, to be repeated eight or ten times during the day. This will more than compensate for the discontinuance of the spray. At night a mouth-guard should be worn for weeks. The most satisfactory guard is perhaps a small piece of adhesive plaster worn vertically across the center of the mouth. Great care should be shown even in babyhood to teach the child to breathe through the nose, the possibility of obstruction being eliminated.

Hemeralopia from Parotiditis.—Among the ocular complications of parotiditis, hemeralopia has not hitherto been reported, writes A. Campani (Gazz. Osped., Aug. 30, 1903), who describes a case in which inflammation of the parotid subsided upon one side, only to be followed by inflammation of the opposite gland and development of dimness of vision toward evening, to which succeeded a total night-blindness; though vision was unimpaired during the day. In the absence of any ocular lesion to which this symptom might be attributed, the author places this case in the category with those hemeralopias of toxico-infectious origin. The author's idea as to the origin of the affection in this instance is borne out by the disappearance of the symptom during convalescence.

THERAPEUTICS.

Antimony in Lung Affections.—If given properly, A. Robin (Bull. General de Therap., Aug. 15, 1903) considers tartar emetic a remedy of almost specific properties in capillary bronchitis and bronchopneumonia. It is best to first withdraw 200 to 250 grams of blood and then to give a tablespoonful of a solution containing 40 centigrams of the drug to 150 grams of water. With a moribund and cyanosed patient with thready pulse, supervision must be very careful and the administration should be stopped as soon as vomiting or diarrhea appear, or when dyspnea increases, collapse supervenes, or the surface becomes cool. Opiates should not be prescribed the same time. It is rare that tartar emetic can be given through an entire day. Generally one must stop and begin again the day after, but with smaller doses. After the severe symptoms have disappeared, another preparation of antimony, the white oxide, does good service in aiding expectoration. While antimony is excellent in forms of pneumonia, where there is a tendency to suffocation, it is a mistake to employ it as routine treatment in this disease.

Oxygen in Surgical Affections.—M. Thiriar (Bull. d. L'Acad. Royal de Med. de Belg., No. 6, 1903) believes that in oxygen we have an excellent body for combating surgical infections without at the same time injuring the cells. He leads the gas directly over the raw surfaces and into the infected tissues, so as to bring about a continuous oxygenation. In the following affections a rapid cure was brought about: (1) Suppurative arthritis of the knee. The pus is evacuated by lateral incisions and the gas then passed through the joint. (2) Purulent and tuberculous peritonitis. (3) Empyema. (4) Gangrene with the formation of gas. (5) Furuncles, carbuncle and anthrax. The gas is here frequently injected into the dead tissue and the surrounding induration.

Protargol in Gonorrheal Disease of the Cervix and Body of the Uterus.—Protargol, as is well known, was originally recommended by Neisser in gonorrhea, in which it was used at first in one-quarter-per-cent. solution, increasing the strength up to one-half per cent. to one per cent. Since then the drug has also been employed in gynecological practice, as well as in diseases of the eyes. V. N. Orloff (Roussky Vrach, No. 31, 1903) used it in 25 women, of whom six had disease of the cervix and eight also affection of the mucous membrane of the body of the uterus. As the infectious principle of gonorrhea tends to spread by continuity of tissue, we can seldom see infection of the uterine mucous membrane without disease of the cervix. The author had to deal mostly with recent infection, so that permanent alterations, either in the body or cervix, had not as yet taken place. Bacteriologically 13 cases gave the diagnosis of gonorrhea, while in the rest the nature of the infection was made out from the undoubted past history. Treatment consisted in swabbing either the cervix or the uterine mucosa with a protargol solution of five per cent up to 15 to 20 per cent; at no time was there ever noted any special irritation. After the swabbing or the injection a glycerin tampon was usually placed at the mouth of the cervix, which was left there for six to eight hours, to be followed by a sublimate or boric acid injection. The treatment was usually conducted every third day. Improvement was noticed after the third or fourth sitting, as was manifested by the diminution of the leucorrheal discharge, both in quantity and in its character. The gonococci disappeared, and the treatment was then limited only to the glycerin suppositories. No complications of any kind were ever observed. There was no marked improvement in diseases of the tubes.

Treatment of Erysipelas.—The contagious character of erysipelas had been known long before its pathogenic bacillus was discovered, and could be easily verified by the extensive prevalence of the disease in certain wards of hospitals. It was Fehleisen, who, in 1883 discovered the streptococcus that causes the disease, and since that time dates our wider familiarity with this affection; its treatment, however, is as yet a more or less debatable ground, for on the one hand prominent authorities recommend the expectant plan,

while on the other a whole array of therapeutic measures has been placed at our disposal to combat the further spread (once the disease has invaded the tissues) of the infection. P. PH. SMOLITCHEFF (Prakt. Vrach, Nos. 29 and 30, 1903) brings forth the names of such surgeons as Dieulafoy, König, Hüter, Wolff and others, every one of whom recommends a different line of treatment. This diversity of views is explained by the fact that a majority of investigators consider erysipelas a self-limited and comparatively benign disease, which can often be treated locally with success, and for this we must have a remedy that is readily absorbable by the skin, and, on being taken up by the deeper layers, is powerful enough to kill the pathogenic streptococcus, or, at least, prevent its further pernicious activity; it must at the same time, when taken up by the systemic circulation, neutralize the existing toxins and fortify the living cells against their invasion, inviting meanwhile leucocytosis to more successfully combat the attack of the enemy; clinically such a remedy should bring about diminution of pain, swelling and heat, prevent the further spread of the erythema and cause the fever to fall perceptibly. As satisfying all the above demands the author finds the alcoholic tincture of iodine of the greatest importance. In view of the fact that the author bases his opinion on experience of twenty years, due weight must be attached to it, for he considers this preparation of iodine specific in a measure that quinine is considered in malaria. The following combination has been especially useful in the author's hands:

℞ Tr. Iodi.....25.0 grams.
Ol. Camphor
Ichthyoli .....aa 12.5 grams.
M. Sig. For external use. Shake before applying.

The application to be successful should be done very thoroughly, and repeated when necessary. Twice a day may be sufficient; if not, the application is done three times daily. Even phlegmonous cases seem to be beneficially affected by the drug.

Empyroform.—Empyroform, a condensation product of tar and formalin, is a dry, non-hygroscopic brownish powder of slight odor. It is insoluble in water, but dissolves readily in acetone, alkalies and chloroform. Employed as such or mixed with zinc and starch it forms an excellent dressing for weeping eczema, according to B. SKLAREK (Therap. d. Gegenw., July, 1903). Other ways of applying it are as ointment, paste and varnish. The application is generally very pleasant, since the itching stops rapidly. Irritation and intoxication, such as fever, vomiting, diarrhea and green urine has never been observed. Patients who cannot stand tar will readily tolerate empyroform if the strength is increased very gradually. Good results were also obtained in psoriasis, prurigo and trichophytosis, and for all forms of eczema it must be regarded a specific far superior to tar itself.

Influence of Nutritive Enemata on Peristalsis.—By studying the peristaltic movements of stomach and intestines in cats that had received nutrient rectal enemata and whose peritoneal cavity was then opened under water, O. LOEWE (Zeitsch. f. klin. Med., Vol. 50, Nos. 3 and 4) finds that with a sufficient amount of opium the small intestines and the stomach will not participate in the movements of the colon and rectum so that the danger of hemorrhage would not be increased in gastric ulcer or duodenal affections. Since, however, the larger part of the injections reach the ileocecal valve, there would be considerable risk in perityphlitis and typhoid. Finely suspended particles, such as dioplets of oil, may rapidly ascend in the gastro-intestinal tract and even reach the esophagus without exciting peristalsis owing to osmotic processes. The danger of a hemorrhage would not be increased by this if non-irritating substances only are used. The influence of injections upon gastric and intestinal secretion has not yet been studied sufficiently, yet it is probable that certain substances as alcohol can stimulate secretions without necessarily interfering with physiological hemostasis.

Phorxal, a New Iron Preparation.—This remedy, but lately introduced for use in anemia and chlorosis, is very highly spoken of by TAUSCH (Berl. klin. Woch., 1903, No. 38). It is a mixture of albuminoid bodies made from the blood cells of cattle and contains a number of organic combinations of iron and phosphorus derived from the hemoglobin, the lecithin and the nucleoproteins of the blood. It comes in the form of a fine powder, odorless and almost tasteless, and soluble in watery liquids. The albumin content is about 95 per cent. The iron is united to an organic group of atoms, derived from the hemoglobin, and one of the advantages of the preparation is that the action of the gastric juice does not disintegrate the material and forms a muriate of hematin, as is the case with the ordinary hemaglobin preparations. It is of value in primary and secondary anemias, and also in those combined with nervous exhaustion. In the latter case its nutritive properties are also to be considered and the usual daily dose of 6 to 10 grams may be doubled or trebled. No unpleasant after-effects were noted in any of the patients.

Treatment of Burns with Glycerinate of Tannin.—In the treatment of burns of whatever degree M. CAPURRANO (Gazz. Osped., Sept. 13, 1903) has found the glycerinate of tannin the most satisfactory substance for local application. If the burn is of the second degree, he empties the vesicles of all fluid and then applies glycerin and tannin in a 50-per-cent. solution, and covers the whole with a dressing of gauze and cotton. The medicament is reapplied several times during the day without removal of the gauze; this being left permanently in place till it becomes detached spontaneously upon formation of the new epithelium. In third-degree burns, sloughs are removed and the same dressing applied. The author attributes the beneficent effect of this treatment to the power of the tannin to coagulate the albuminous substances of the tissues and thus form a protective coating; and also to the antiseptic qualities of both tannin and glycerin.

Gastric Contents in Gastroptons.—Although it has been recognized by all observers that the gastro-intestinal symptoms are usually the most marked manifestations of enteroptosis very little work has been done in regard to the motor, chemical and sensory disturbances of the stomach in this condition. T. R. BROWN (N. Y. Med Jour., Sept. 26, 1903) has made careful examinations of the stomach contents in 20 cases of gastroptosis and for purposes of comparison has divided them into three series: Those with slight dilatation, those with moderate dilatation, and those with considerable or extreme dilatation. Nearly all cases gave marked symptoms of neurasthenia, the character and severity of the symptoms not depending upon the amount of dilatation. Although the series is a small one the results which he obtained would suggest that in simple gastroptosis there is a slight diminution in the amount of free hydrochloric acid in the majority of cases; where the dilatation is moderate the free hydrochloric acid is still further reduced, while in those cases associated with marked dilatation an absence of free hydrochloric acid is the usual occurrence. Gastroptosis *per se*, therefore, seems to lead to very slight diminution of the free hydrochloric acid.

SATURDAY, NOVEMBER 14, 1903.

PRESENT NEEDS OF THE MEDICAL PROFESSION.

IN his address as the retiring President of the New York State Medical Association, delivered at the recent meeting of that body, printed in full in the November number of the *Journal of the Association*, Dr. Frederick Holme Wiggin calls special attention to certain crying needs of the medical profession in our generation that must be attended to if there is to be any amelioration of evils long complained of, but still continuing.

He shows that although much has been done to organize the medical profession in this country there are still, according to the secretary of the American Medical Association, more than seventy-five thousand physicians in the United States who are not at present members of any medical organization. If present-day evils are to be eradicated, more universal union of the profession is absolutely demanded. How this can be brought about remains one of the serious problems that those who have the best interests of the medical profession at heart must endeavor to solve.

Dr. Wiggin considers that it is evident that there is a necessity for a change in the form and attractiveness of existing medical organizations, if it is desired to unite the members of our profession in a few strong and closely allied societies. He quotes Sir Victor Horsley, M.D., who, in a recent paper, said "Organizations, medical or otherwise, are purely temporary; their only purpose is to meet the needs of the moment and when those organizations fail to keep pace with the natural evolution of the circumstances under which we have to live, it is quite clear that we ought to reconstruct the various machines that we have in operation." As Dr. Horsley has had very extensive experience in recent years as to medical organization, in various attempts to reorganize the British Medical Association in such a way as to make it effective for professional purposes, his words should go far in the matter.

He considers that at the present time, there are two professional requirements, social and scientific. Under the social requirements are placed the right to practice, defense from unjust attacks and the enforcement of our rights by the prosecution of illegal physicians.

Here in New York, much has already been accomplished beyond what has ever before been attempted as regards some of these social requirements. The defense of physicians against blackmailing suits for malpractice is now assumed by the New York State Medical Association for all its members, and already the rule is that, in most cases, suits never come to trial, for the plaintiff realizes the futility of fighting legally with a large and powerful medical association and also feels that much of the sympathy that ordinarily goes out to the plaintiff on the part of the jury in these cases is neutralized by the fact that the defendant is a physician in good standing and that brother physicians are united in his defense.

When medical societies generally shall have adopted this system introduced by the New York State Medical Association they will doubtless see the same encouraging increase in membership that has followed the diffusion of the knowledge with regard to defense against blackmail here in New York State.

Undoubtedly there are other features of medical society life that will admit of improvements calculated to make the membership of these bodies not only larger but more united. As at present constituted, proceedings are often too formal and the social side of organization is not sufficiently cultivated. Commonly to have members of the profession meet on a plane of sociability is to get rid of many of the temptations to friction in practical life and obviate in the easiest possible way by prophylaxis infractions of medical ethics.

While meetings are primarily intended for mu-

tual help from a scientific standpoint and for the rapid, easy diffusion of medical advances, it must not be forgotten that physicians do not cease to be examples of the animal sociale and opportunities for the cultivation of the amenities of life must be afforded.

The close union of interests that could be thus secured, if all the practising physicians of this country were brought into intimate contact with brother practitioners, would redound not only to the benefit of the profession but also to that of the public by more effectual regulation of medical abuses. Those sincerely interested in medical advance and in the public welfare owe it to themselves to spare no effort in this direction with the purpose of securing efficient medical union as the greatest crying need of our time, and in itself the solution of most of the other medical abuses of which we hear so much complaint.

GEOGRAPHY AND INSANITY.

Mental disease as a medical entity and insanity as a social disorder should be regarded separately if a due appreciation of the many features, medical and sociological, is to obtain.

It has been the custom of many who have not borne these distinctions in mind to misinterpret statistical inquiries bearing on this subject not only in this country, but in Europe also. As a result there obtains a widespread belief that insanity, as a medical entity, is greatly on the increase, whereas a much more correct interpretation would be that the great increase in the number of inmates of asylums is due less to medical than to social factors which are capable of putting an entirely new face on the interpretation of the statistics.

One of the most apparent of those social factors is the diminishing dread of putting one's friends in a madhouse. Modern palaces with all the conveniences of our best hotels are now offered to an indigent population and it is little wonder that this single feature has encouraged the placing of many in institutions who heretofore have been taken care of at home and have not entered into statistical summaries.

A still more important factor is correlated with the former. The increasing population causing the fierce combat in urban communities drives unfortunate sub-producers out of a family circle, the privilege of which, by reason of many ties, they have been permitted to enjoy. From being family dependents they become community parasites and thus contribute to swell the apparent tide of increase. Other and more complex social factors are constantly at work all tending in the same direction and lead to the hasty assumption on the part of the lay public of an unparalleled increase in the amount of medical insanity.

At the present time there is almost no method by which the relative importance of these factors may be ascertained. Our statistical methods in medicine are crude beyond belief, and it is more than doubtful that without an unpractical increase in their complexity can trustworthy results be obtained. Given those we do possess, however, it is significant and hopeful that the figures of the United States Census Bureau can be made to yield a number of important preliminary results leading to a more correct understanding of some of these social factors, and what is still more important, the interpretations seem to afford sufficient ground on which to base rational legislation looking toward the amelioration of some of the unnecessary consequences that our country as a whole must suffer from existing social regulations.

The study to which we refer is on the "Geographical Distribution of Insanity," first published in part, in the *Journal of Nervous and Mental Disease* and now completely, with illustrative maps, in the *National Geographical Magazine*, October, 1903, by Dr. William A. White, the recent appointee to the superintendency of the Government Hospital for the Insane at Washington—a fit preliminary study certainly for one in such a central position.

The influences of climate, natural physical topography, rain-fall, and other purely meteorological conditions are severally considered and are very wisely referred to a secondary and mediate position in the interpretation of the geographical distribution of these diseases. In the mental factors involved in the struggle for existence are to be found the primary causes of mental deterioration and breakdown; concomitant conditions of civilization being responsible. One of the most apparent features connected with the movement is the concentration of population in a certain restricted area. The North Atlantic division bears the brunt of the evil effects of this massing of struggling humanity—particularly in the large cities; the proportion of insanity being in direct ratio with this larger factor. The movement of the population, both as a factor of growth and as a factor in mental decay, has certain features in common, which are well brought out in Dr. White's studies.

We cannot summarize, save at great length, this careful and thoughtful presentation, but the question of the distribution of insane immigrants is of practical legislative interest. Dr. White shows that fifty per cent. of the 25,000 insane of New York State are foreign born. This has resulted from the indiscriminate taking in of the offscourings of Europe. This—unrestricted immigration—is one of the great ulcers in the social disease of insanity—only exceeded by the greatest curse that can afflict a nation—war.

We can commend this paper most earnestly to physicians, politicians, and legislators as one worthy of the most careful consideration in the study of the relation of mental breakdown to healthy national life.

EDITORS AND THEIR CONTRIBUTORS.

We sympathize with the attempt of the *Boston Medical and Surgical Journal* to extricate itself from the embarrassing position in which it recently placed itself by publishing a pseudo-scientific paper on the ill health of the historian, Francis Parkman. The paper was an exceedingly ill-conceived and ill-executed attempt to show that Parkman owed his poor health to the alleged fact that he had not worn the proper kind of spectacles. It was in line with a series of papers by the same writer—a Philadelphia ophthalmologist—in which the desperate attempt has been made to attract attention to an overridden theory by affecting to show that Darwin, Huxley, Carlyle, Wagner, and some other celebrities were the victims all their lives to their having neglected to correct an alleged eye-strain.

With the character and purport of these papers we do not intend to concern ourselves in this place. We are content to leave them to the judgment to which the scientific world will undoubtedly subject them, and to the oblivion to which it will eventually consign them. We have no relish for the task of writing them down. Such would be a work of supererogation in the case of literary products which are foreordained to perish. The moral we wish to point is one which concerns the relation of an editor to his contributors.

We take it as a fact that an editor's duty does not end with his merely disclaiming responsibility for the opinions expressed in a paper which he accepts for publication. His duty certainly does not end there. When he publishes a paper he, of course, does not assume responsibility for the opinions conveyed in it, but he does assume some measure of responsibility for giving them currency. Otherwise the editorial function would be reduced to the mere task of *accepting*, instead of *selecting*. The selective function is, in truth, one of the highest functions of an editor. In it are involved important duties to his contributors, to his readers and to his journal.

It is not always the simplest matter in the world to distinguish the chaff from wheat in the articles contributed, nor can the editor always have the clairvoyant power to detect the many motes that mar some productions. But it is one of the most important of his functions to try to detect the lack of both moral and scientific qualities in the papers that are submitted to his judgment. Herein lies a fine ethical question, in the solving of which the editor has a profound duty to his readers.

The subject is clearly illustrated in the case of the *Boston Medical and Surgical Journal;* although we do not doubt for a moment that our contemporary is suffering from a temporary lapse of judgment rather than from an intentional fault. Having published this questionable paper, it indulged in some mild critical comments, and was immediately taken to task by the writer of the paper, who insinuated that the editor in criticising one of his contributors was guilty of a discourtesy to a guest. The contention is, of course, absurd; and, moreover, it has nothing to do with the question of the health of the historian Parkman, or with the kind of eye-glasses he wore. It has also nothing to do with the question of the eye-strain of Mr. Darwin or Mr. Huxley or anyone else, nor even with the "thousands of cases" which have been quite miraculously cured of many frightful diseases by the imposition of Philadelphia spectacles. But it has the desired effect of putting the editor on the defensive, and he is disgusted to find that he must use his critical faculty to defend himself, instead of having originally used it to consign the author's screed to the waste-paper basket.

We live in just the age for these things. The times are prolific in all sorts of "healers" who play their antics, literary or oratorical, before the public in their own ways. Dowie and Mrs. Eddy are, of course, outside the pale of rational criticism; but unfortunately there are spectacular prophets within the ranks of the medical profession itself, and these do not scruple to distort facts, to originate fantastic theories, to use exaggerated language and to indulge in coarse invective, Dowie-like, against those who can detect at

a glance their crude follies. Criticism is wasted upon such extremists as these; but every medical editor should know, what the *Boston Medical and Surgical Journal* is now finding out, that one of his duties is to protect, as far as possible, his readers by excluding from his columns those papers that do not bear the stamp of conscientious methods of analysis.

THE REAL PLACE OF ALCOHOL IN MEDICINE.

An aspect of the subject of the physiological effects of alcohol, that appears to be ignored or neglected by those who have done most to illuminate it, is its course and chemical changes after ingestion.

It is well known that alcohol is rapidly taken up by the stomach and intestinal branches of the portal vein, and thence is conducted to the liver, where it is partially or wholly oxidated. In the instances when a quantity is imbibed which is in excess of the capacity of the liver cells to oxidate, the surplus alcohol, being passed on to the heart and general circulation, then recommences oxidation after the return from the lungs to the left heart, which continues until it is consumed.

Alcohol is a very high oxidant, *i.e.*, it is very inflammable and possesses a high affinity for oxygen, also it is very diffusible, and environmental bodies are very prone to become impregnated by it.

When alcohol is ingested, diluted, or in combination with foodstuffs, its absorption and oxidation are very much slowed and the saturation of the other substances, by the alcohol, results in a combined oxidation of average duration and intensity, both consuming together. Thus we have illustrations of the influence of diffusibility upon combustion. In sweet wines and beer we have examples of this slower combustion.

In whisky and brandy we have illustrations of highly alcoholic non-saccharine beverages, which when imbibed undiluted, and consumed in moderate quantity, undergo active portal combustion, thus utilizing more or less of the available oxygen of the portal blood, or, when taken in immoderate amounts, in exhausting the portal blood, and hence depriving the tissues of oxygen, adequate for their normal katabolism, and serving simultaneously in thus lowering the general volume of blood oxygen.

We have vivid illustrations in habitual drinkers of general fatty overproduction and especially fatty degeneration of the liver cells; and in heavy drinkers, of the above, together with endocarditis of the left heart, and sclerosis and atheroma of the aorta and arteries, and capillary fibrosis. The general suboxidation is attended with general tissue softening and more or less colloid degeneration, which, together with urea and uric acid excess, are the principal causes of vascular obstruction and high blood pressure. These conditions may also be aggravated by the ingestion of meats containing an excess of uric acid, when the systemic oxidation is too low to accomplish its combustion; and by other associated causes of lowered oxidation.

It has long been observed that gout is common to sweet wine and beer drinkers, and that the imbibers of the more diffusible and higher oxidants whisky and brandy are immune. Thus it is that highly diffusible liquors saturate, and enhance the oxidation of, the less oxidizable foods, and the colloid and uric acid products of the body suboxidize disintegrations, while those in sugar combination, owing to their lower diffusibility, but yet of higher combustibility than other foods, serve by their hyperactive combustion, in thus depriving other, principally the nitrogenous foods, of an amount of oxygen adequate to their complete metamorphosis.

The fact that alcohol lessens general oxidation and hence the general metamorphosis of tissues and foodstuffs, and thus acts as a "saver of proteids," does not warrant the statement that alcohol is or acts as a food. It appears to be a great mistake to confound or place in the same category, the elements of nutrition, and agents which cause a stagnation in the processes of katabolism of the tissues, or of the oxidative metamorphoses of foodstuffs, for, manifestly, these latter ones are pathogenic processes and lead to grave maladies.

Certainly, the supply of food, and the processes of its metamorphoses, are not analogous and neither can it be said that nutrition can be maintained or even sustained by retarding oxidation. It is observed that many diseases of suboxidation are attended by wasting and even marasmus; in fact, the increase of lean tissue, by such measures, is rarely if ever attained, while conversely the body-weight, thus heightened, is due to fatty deposit, more or less of which is at the expense of lean tissue. A diminished appetite thus produced, while it lowers the demand for food, does not maintain the same nutrition, as though the additional food had been ingested and normally appropriated by the tissues. In accepting protoplasm as the bases of life and index of nutrition, we must reject alcohol as a *food* or nutrient.

That alcohol does by its superactive combustion consume the available oxygen of the portal blood, and thus lower general oxygenation, is attested by the sclerosis (burns) of the hepatic cells and the lowering of the general temperature following its ingestion. The immediate effect of alcoholic beverages is increased warmth, parallel to its alcoholic percentage content, followed by a corresponding fall of temperature.

The true place of alcohol in medicine, then, is as a transient, highly diffusible stimulant, incident to its active portal oxidation, and *directly,* as an oxidant, for the purposes of clearing the portal circulation and for assisting the hepatic combustion of certain foods, which, as above mentioned, is accomplished by the more diffusible (highly alcoholic) liquors.

In clearing the portal circulation the active combustion of alcohol acts similarly to that of the fruit acids, which are so popular among hearty eaters for this purpose. For the restoration of appetite and digestive ability, which formerly was afforded by an orange or lemon, the advanced epicure finds the more highly diffusible and combustible cocktail necessary, with which to precede his meal.

Medical men can and do make legitimate use of alcoholic liquors for the above therapeutic ends, and by regulating the amounts and varieties, the time of taking, in relation to food, etc., maximum good and minimum evil can be attained, in appropriate cases. Continued tippling and periodic sprees are almost equally degrading to the body as a whole. The ignorant or rash uses of alcoholic beverages are the chief causes of mischief which is due to them. There can be no doubt but what all points taken into consideration, the race as a whole would be far better off without them.

The many diseases due to inebriety, it will be observed, are of the degenerative type and are all due either to hypercombustion (fibrosis, sclerosis) or to suboxidation, viz., all kinds of degradations and degenerations of the brain, nervous, muscular and vascular systems.

ECHOES AND NEWS.

NEW YORK.

The D. W. Harrington Lectureship, University of Buffalo.—The Medical Faculty of the University of Buffalo has chosen Dr. Samuel J. Meltzer, of New York, to deliver these lectures for 1903. The subject selected by Dr. Meltzer is "Edema, a Consideration of the Physiological and Pathological Factors Concerned in its Formation." The lectures will be delivered in the Medical College, November 30, and December 1, 2, and 3, at 5 P.M. The medical profession is cordially invited to attend. These are the first lectures given on this foundation. Lectures will be given as often as the income from the fund will warrant.

Professor Lefferts' Gift to Columbia Medical School.—Dr. George M. Lefferts, who has announced his intention of retiring from the Chair of Laryngology on June 30 next, when he will have finished thirty years of academic service, has presented to the University his extensive and valuable collection of apparatus for illustrating the teaching of laryngology and rhinology. The Trustees ordered that the apparatus should be hereafter known as "The Lefferts Collection."

New Professors at Columbia.—Five new professors in medicine were appointed, the first two of whom are to have seats in the Medical Faculty. The appointees are Drs. Samuel W. Lambert, Professor of Applied Therapeutics; Joseph A. Blake, Professor of Surgery; George E. Brewer, Professor of Clinical Surgery; John S. Thacher, Professor of Clinical Medicine; Frederick Peterson, Professor of Psychiatry.

New Hospital Pavilion.—At a recent meeting of the Board of Managers of St. Luke's Hospital, the president, George MacCulloch Miller, announced the desire of Mrs. Margaret J. Plant, to erect and present to the institution an additional pavilion, thus pursuing the line of development laid down in the plans for the erection of the ten pavilions, five of which have already been built. The new pavilion, as announced in the Medical News of last week, will be for the care and treatment of private patients, and will be located on the southeast corner of the block overlooking Morningside Park. Mrs. Plant's gift solves a problem of long standing for St. Luke's. Since the hospital was moved from Fifty-fourth street to Cathedral Heights, private patients have been cared for on the two upper floors of the Vanderbilt pavilion. The facilities for the care of patients in this building have been inadequate, and the nurses have been cramped in their quarters. The development of the hospital was absolutely checked by this situation. Now the management will be enabled to open wards which, by reason of lack of income have been closed, and thus enlarge the charitable work of the institution.

Obituary.—Drs. O. A. White and L. P. Walton.—At a meeting of the Medical Association of the Greater City of New York, held November 9, 1903, the report of a committee, appointed to prepare a suitable minute on the death of Dr. Octavius A. White, was received and adopted. It was devoted to a eulogium of the character and eminent services of the deceased, and included the following tribute quoted from the Oakland (Cal.) *Tribune*, of May 28, 1903: "There has just died in New York, one of the greatest of the heroes produced by the Civil War; yet his name is absolutely unknown to ninety-nine out of every hundred of his countrymen. This hero was Dr. Octavius A. White, famous as a yellow fever expert. When yellow fever attacked the Federal prisoners at Florence, South Carolina, his attention to them was tireless. All during the terrible years of civil strife he was indefatigable in healing the sick and wounded of both armies, and risked his life and health in the pursuit of his high calling with greater frequency and daring than any soldier in the field. It is a commentary on the unequal division of the awards of merit, in popular estimation, that the heroism of such a man should be passed over and forgotten by the mass of men, while the deeds of hundreds of lesser men, who sought

to slay or win glory on the battle-field, are commemorated in marble and bronze. . . . We raise monuments to those who kill, and leave unmarked the tombs of those who cure." The conclusion of the report was as follows: "With a public life full of noble achievements for suffering humanity and a home life illumined by the most charming of domestic traits, his memory will be cherished for years that are to come by all who knew him. Your Committee, in presenting this minute, unanimously offer the following resolutions:"

Resolved, That in the death of Dr. Octavius A. White this country and community have lost a valued citizen and our profession of medicine an honored member.

Resolved, That we extend to the bereaved family of Dr. White our profoundest sympathy for them in this their period of bereavement. "Vivat Post Funera Virtus." (Signed) Thomas E. Satterthwaite, John G. Perry, Reynold Webb Wilcox, Committee.

Dr. Luis P. Walton was among the earliest members of this Association. Born in England fifty-odd years ago, he came to this country with his family at an early age. He was educated here, having been graduated at Columbia College in 1863 and at the College of Physicians and Surgeons in 1870. His death, which was sudden enough to be almost tragic, occurred in London early in September of this year. He was one of the few representatives of the old school of general medical practitioners, and in that capacity he occupied a position of peculiar confidence and affection in the hearts of a large number of patients. They sought his advice in many other matters besides those appertaining to their physical ills, and they always found in him a patient and sympathetic listener and a sound and earnest adviser. Few who have not been general practitioners themselves can realize the extent of the responsibility and of the unremitting toil involved in caring for a clientele as large as his. He was a genial, kindly gentleman of wide sympathies and general interests, with a vigorous, active, masculine intellect; always cheerful, courageous, sympathetic, and ardently devoted to his friends. For public professional honors and appointments he cared but little, but he was ever loyal to the profession of medicine and generous in his dealings with its members. The suddenness of his death was very shocking to his family and friends, who were wholly unprepared for it; but it was exactly the kind of ending which he would have chosen for himself. Although well aware that such an end was not unlikely from the persistence of certain symptoms whose gravity he did not underestimate, he was uncomplaining, patient, heroic, with a depth and earnestness of character well known and recognized by his intimates; possessed of a shrewd and droll humor and a remarkably alert intelligence. His affectionate devotion to the land of his birth, which amounted almost to a passion, never made him unfair to the land of his adoption, and always inspired respect among those who knew him best. George L. Peabody, Henry S. Norris, Committee.

Dr. Emil Rosenberg, who died Wednesday at his home, 138 West Eighty-fifth street, was known through this and other countries as an authority in the medical examinations of applicants for insurance policies. He was seventy-four years old and came to this country from Germany in 1868, since which time he had been the senior medical examiner of the Northwestern Mutual Life Insurance Company. He was a prominent member of the German Medical Society and other scientific bodies.

William B. O'Rourke, Superintendent of the Metropolitan Hospital on Blackwell's Island, died at the hospital last week from cancer of the stomach. He was born in this city fifty-five years ago. When he was thirteen years old he entered the Harlem Railroad machine shops as an apprentice, working under Richard Croker, who was foreman. Later he became chief machinist in the shops and after that was appointed inspector of boilers in the United States Steamboat Service. In 1890 Mr. O'Rourke was appointed steward of the Homeopathic Hospital on Ward's Island. The next year he became warden of Bellevue Hospital, which position he retained until 1896. In 1898 he was again appointed Warden of that institution.

PHILADELPHIA.

College of Physicians.—The College of Physicians of Philadelphia, at the recent meeting, authorized the president, Dr. Horatio C. Wood, to appoint a committee of eight, including himself, to arrange for the preparation of plans for the new building the college proposes to erect on the new lot purchased last spring. The college has a nucleus of $24,000 for its building fund.

Cures by Lorenz Method.—It is stated that Dr. James K. Young is confident that three-fourths of the operations by Philadelphia surgeons, by the Lorenz method, for congenital dislocation of the hip will prove effective. The cases operated on here, by Lorenz and local surgeons, exceed 50 in number, and Dr. Young believes that more than 40 of the reductions have been successfully accomplished. Patients here seem to respond more readily to treatment than do those in Austria. These views are of course based on the progress of the cases thus far in their treatment.

Vaccination Urged.—The authorities of the Health Department are unceasingly urging upon the people of the city the necessity of vaccination. The outbreak of smallpox which has lasted for several weeks shows no signs of abatement. During the forty-eight hours previous to the time of writing this letter, 13 new cases were reported. Numbers of the public school buildings are being closed temporarily for disinfection. A representative of the Bureau of Health has lately visited the various medical schools of the city in order to vaccinate any students desiring such protection. This was entirely optional on the part of the students.

Streets to be Cleared of Beggars.—Orders have been issued to the police of the city to enforce the laws relative to clearing the streets of beggars, tramps, fakirs and station-house lodgers. This move followed a conference between a committee from the Philadelphia Society for Organizing Charity and the Director of Public Safety. It is believed that if the laws are enforced the begging population will fall into three classes: (1) Many will disappear; (2) some will find their way to the places provided by the city for those who have no home nor means of support; (3) exceptional cases for which charity can and should provide will be looked after by the Society. To dispense with police-station lodgers, the Society will furnish policemen with tickets admitting homeless men and women to their two lodging houses where a bath, bed and two meals will be furnished for three hours' work.

National Association for the Study of Epilepsy.—The annual meeting of this society was held at the College of Physicians, Thursday, November 5. The address of the President, Dr. Wharton Sinkler, dwelt upon the necessity for organized and concentrated effort against epilepsy and stated the purposes of the Association. Among the most important of the number of papers that were read were those of Dr. J. Chalmers DaCosta and Dr. John C. Munro regarding the operative treatment of epilepsy. Both

speakers asserted that operations for the attempted relief of epilepsy are entirely too numerous. Dr. William N. Bullard, of Boston, was unanimously elected President for the ensuing year. The other officers were reelected.

Hebrews Plan New Hospital.—A movement originated some time ago among the Jewish residents in the southern part of the city for the erection of a new hospital has recently taken definite shape. The Mt. Sinai Hospital Association has purchased on the east side of Fifth street, between Reed and Dickinson streets, a lot 88 by 241 feet in size. On this it is proposed to erect a modern hospital to cost at least $100,000. One of the principal reasons for establishing the hospital is the distance from that locality of the Jewish Hospital in the northern portion of the city.

Compulsory Vaccination in Allegheny.—As one of the sequels of the recent investigations in Allegheny City the Board of Health has instituted compulsory vaccination in that city. Dr. Benjamin Lee, Secretary of the State Board of Health, says it is the first occasion in recent years in which compulsory vaccination has been enforced in a large city in Pennsylvania. The records show that last month there were in Allegheny 87 cases of smallpox and 22 deaths, hence the direction of the State Board is absolutely compulsory.

Home Study.—Superintendent of Schools Brooks has sent a circular to the principals of the elementary schools calling attention to the amount of home study to be assigned to the different grades. The rules are as follows: First. In the first and second grades, no home study is to be assigned. Second. In the third grade not more than half an hour, and in the fourth grade not more than three-quarters of an hour of home work is required. Third. In the fifth grade, not more than one hour; in the sixth grade, not more than one and a quarter hours; in the seventh grade, not more than one and a half hours, and in the eighth grade, not more than from an hour and a half to two hours of home work is required. These are maximum limits of time not to be transcended for any reason whatever. If any teacher assigns home work requiring more time than specified above, she is not complying with the direction of the Superintendent, based upon the action of the Board of Education.

Obituary.—Dr. Franklin Van Artsdalen, a well-known physician of this city and Lower Merion Township, died at his home November 5, aged sixty-nine years. He graduated from Jefferson Medical College in 1856. The deceased was prominently identified with many secret societies, particularly the Masons and Odd Fellows.

CHICAGO.

Chicago Surgical Society.—At the annual meeting of this Society, held Oct. 19, 1903, the following officers were elected for the ensuing year: President, Dr. E. Wyllys Andrews; Vice-President, Dr. Malcolm L. Harris; Secretary, Dr. A. E. Halstead; Treasurer, Dr. Daniel N. Eisendrath.

Oak Leigh Educational Sanitarium.—A new sanitarium has been opened at Lake Geneva for the treatment of children suffering from nervous and mental affections. The institution, which is now under the private supervision of Dr. Mary E. Pogue, former resident physician of the Illinois Hospital for Feeble-minded Children, will be known as the Oak Leigh Educational Sanitarium, and the object will be to meet the present needs for the treatment of the mentally deficient children. The aim of the sanitarium will be to correct the causes of deficiency, if possible; to house the unfortunate children in attractive hygienic surroundings; to educate them in the line of work to which each child responds most readily, and to prepare them for living rather than to incarcerate them for life. Supporting Dr. Pogue, as a supervisory board, are Drs. Daniel R. Brower, Sanger Brown, Archibald Church, W. S. Christopher, Homer E. Halbert, and Wm. G. Stearns. The sanitarium is the offspring of an idea of friends of the Children's Hospital at Lake Geneva to establish and affiliate it with some such institution, but a lack of funds made this impossible. Kindergarten, medical and corrective gymnastics, the correcting of speech defects, articulation, counting of beads, and the less exhaustive methods of mathematics, modeling in clay, basket and mat weaving, and the control and understanding of self are to be taught, each child receiving individual instruction. This is a most commendable enterprise and much needed, because physicians in Chicago are being constantly called upon to recommend institutions for the treatment of mentally defective children.

Case of Blastomycosis.—At a meeting of the Chicago Medical Society, held Nov. 4, 1903, Dr. E. A. Fischkin reported and showed a case of blastomycosis. The patient was an Italian, fifty-one years of age, whose family history was negative. His wife and children were healthy. Patient had had a keratosis on the side of his nose for fifteen years without undergoing any change. The present disease began in May of this year. A pimple appeared near the external corner of the eye; he scratched it with his finger, shortly after which it became sore and began to enlarge. A similar lesion appeared on the back of the neck. When patient first presented himself, the lesion around the eye covered an area of about three-quarters of an inch in width and one inch in length, extending from the lower eye-lid and encircling the external canthus and reaching the upper lid. A photograph of this stage of the disease showed the extent of the lesion. Under potassium iodide and X-ray treatment the patient has shown marked improvement. Patient is still under treatment.

The Mechanical Methods in the Cystoscopic Treatment of Kidney and Ureteral Diseases.—Dr. Gustav Kolischer read a paper with this title before the Chicago Medical Society, saying that the direct local treatment of ureteral and kidney diseases, by the aid of the cystoscope and the ureteral catheter, is not as popular among the surgeons as should be expected. Possibilities of this method may be summed up as follows: Cases of pyelitis, especially those of gonorrheal origin, will heal under repeated flushings of the kidney pelvis through the ureteral catheter. Impacted ureteral gravel can occasionally be loosened by the ureteral sound. The same holds good of ureteral stones. The author's method of running a catheter up to the impacted stone and then injecting vaseline oil, has often been successfully employed by the essayist and others. This method in releasing the impaction meets a vital emergency in removing the cause of reflectoric, bilateral anuria without exposing the patient to so dangerous an operation as ureterotomy. Ureteral catheterization and flushing may be used in order to remove pus plugs. Certain cases of ureteritis can be cured by injecting antiseptic solutions into the diseased part of the ureter. The results in ureteral strictures are still far from satisfactory on account of technical

shortcomings. Occasionally, a laterally located ureteral fistula can be cured by a permanent ureteral catheter. The question arises: Is the favorable influence of this method on certain cases due to any specific action of the fluid used, or simply due to mechanical influences? The author is inclined to favor the latter explanation, for the reason that pyelitis cases will rapidly improve, especially so far as the general condition of the patient is concerned, although only indifferent fluids were used for the flushing. Patients, carriers of ureteral stones, improve rapidly and stay in this improved condition for a long time, although the repeated flushing of the ureter with the indifferent fluids didn't dislodge the stone or the calculi at all. The author tries to explain these facts by the following theory: In an inflamed renal pelvis, or around an impacted ureteral calculus, pus and débris will be precipitated and accumulated. Decomposition in these masses will lead to the formation of toxines and subsequent absorption of those into the system. Therefore, the appearance of certain symptoms which will disappear after repeated flushing has removed these infectious deposits. Decomposition, absorption and the reappearance of the symptoms will recur if newly formed deposits are again precipitated. Although the author expects improvements and more numerous and more satisfactory results from these methods, he wants to caution against any overflow of enthusiasm and against reports which are more enthusiastic than are apt to stand for a rigorous criticism.

The Limitations of the Practical Value of Urethroscopy.—Dr. Louis E. Schmidt said that the achievements of urethroscopy has been gained from two directions. The cognizance of certain facts has been obtained by comparing and studying the findings of the superficial appearance of the urethra during operations and autopsies. Their pathological changes were made to coincide with these, so that deep seated as well as only superficial changes, are to be correctly diagnosed by determining the correct urethroscopic image. Experience has positively shown that urethroscopic examinations not only have often been useless, but that frequently repeated urethroscopic manipulations have been distinctly harmful to the general condition of patients. The urethroscopic tube of appropriate size should admit of easy introduction. If small (in diameter) tubes are used, the sought-for information is not easily gained, while if a sufficiently large tube is employed and forced through very dense infiltrations, distinct reaction will follow, probably due to the carrying of infection to the deeper layers. There is an actual demand for urethroscopy during the course of a large number of cases of chronic gonorrhea. Those cases that cause one to believe that one of certain localized processes are present and which do not yield to routine treatment. The localized processes may be infiltrated ulcerations with a depressed center, hard granulations, coated fissures, encircling rigid infiltrations, involvement about and within the urethral glands or other processes which tend to occur in patches.

Superficial Ulcerations.—Here the long and light gonorrheal threads are not found, but irregularly shaped flakes, usually thicker in the center and even dark in color, microscopically shown to be blood, will be found to float in the urine. The involved areas can only be correctly located with the urethroscope. The presence of coated fissures may be strongly suspected if patients observe, after a nocturnal pollution or after the sexual act and frequently after each urinary act, a distinct shock always in the same place and continuing for some time. Here again the urethroscope can be of service. Stubborn granulations are to be suspected whenever regular sounding produces more or less profuse hemorrhage each time. As a rule these granulations will not yield except to heroic treatment through the urethroscope. Infiltrations of greater extent and rigidity manifest themselves by the appearance of a more catarrhal secretion. It is important to locate these infiltrations and to diagnose their character, because different infiltrations call for an entirely different mode of treatment. The diagnosis and indications are made with the urethroscope. Another group of symptoms, those of a sexual character, forcibly suggest the use of the urethroscope.

American Electro-Medical Society.—The first annual meeting of this Society will be held December 1, 2, and 3, at the Masonic Temple, Chicago. This society, which already numbers over one hundred and fifty members, has for its object "Investigation in Electricity and Allied Sciences, and the Encouragement of their Application to Medicine and Surgery by the Formation of District and Local Societies." Papers will be presented by Dr. John B. Murphy, Chicago; Dr. Byron Robinson, Chicago; Dr. G. Betton Massey, Philadelphia; Dr. C. S. Neiswanger, Chicago; Hon. John M. Smulski, city attorney for Chicago; Dr. J. Rudis-Jincinsky, Cedar Rapids, Iowa; Dr. H. Preston Pratt, Chicago; Hon. Edward B. Elliott, city electrician for Chicago; Dr. Clarence Skinner, New Haven, Conn.; Dr. J. N. Scott, Kansas City, Mo.; Dr. R. S. Gregg, Chicago; Dr. Mirhan Kassabian, Philadelphia; Dr. T. Proctor Hall, Chicago; Dr. A .D. Rockwell, New York; Dr. Carl S. Beck, New York; Dr. Heber Robarts, St. Louis, Mo.; Dr. John E. Gilman, Chicago; Dr. Chas. G. Davis, Chicago; Dr. O. P. Clemensen, Chicago; Dr. J. P. Hetherington, Logansport, Ind.; Dr. C. W. McMichael, Chicago; Dr. O. S. Barnum, Los Angeles, Cal.; Dr. Elmore S. Pettyjohn, Chicago; Dr. Geo. F. Hawley, Chicago; Dr. John E. Harper, Chicago; Dr. Lloyd Hammond, Chicago; Dr. F. A. Leusman, Chicago; Dr. C. D. Collins, Chicago; Dr. Hamilton Forline, Chicago; Dr. R. H. Bartlett, Chicago; Dr. H. P. Fitzpatrick, Chicago.

CANADA.

Want Tuberculosis Dispensary Established in Montreal.—At a recent well-attended meeting of the Investigation Committee of the Montreal League for the Prevention of Tuberculosis, a resolution was unanimously passed favoring the establishment of a dispensary in that city for cases of tuberculosis.

Public Health and Railway Cars.—Assurances have been given by the superintendent of dining, parlor and sleeping cars of the C. P. R.R. in Canada, that everything in connection with their service is kept in a satisfactory clean condition. After a run across the continent all these coaches are cleaned by the compressed air system, and every ten days all these cars are thoroughly disinfected, and fumigated by means of formaldehyde. If any contagious disease is known to have been carried by any particular car that car is immediately put out of commission, and not used again until it has been satisfactorily disinfected. When a supposed consumptive has occupied any of these coaches the linen and blankets utilized are subjected to a separate washing, with an absolutely irreproachable disinfection.

Action Taken Against Physicians.—The Pharmaceutical Association of the province of Quebec has

laid charges in the Police Court of the city of Quebec against a number of the physicians of that city who have been in the habit of giving their prescriptions to unlicensed druggists or to unregistered drug clerks. Actions have also been entered against several druggists accused of selling poisons to the public contrary to the provisions of the Pharmacy Act.

Changes in the Quebec Medical Act.—The College of Physicians and Surgeons of the Province of Quebec have decided to recommend at the next meeting of the legislature of that province that their Medical Act shall be amended to provide for a five years' course of medicine instead of four as at present prevails. They will also advise that the clause providing for the registering of those holding English degrees without further examination in Quebec shall be rescinded. In addition to this it will be recommended that the requirements for matriculation for French students shall be a B.A. degree, and for the English as at present holds.

Manitoba Medical College.—The Manitoba Medical College began its present session with the largest freshman class in its history. This numbers something over forty, and it is the twenty-first session of the College. The most prominent feature of the Medical Act of the province of Manitoba is that those receiving degrees from their provincial university shall not be required to pass an examination before the Medical Council of the province. All they have to do is simply to register, present their diploma and pay the necessary fee of $75. For the present session the following changes have been made on the staff: Dr. J. O. Todd has been appointed Professor of Anatomy in succession to the late Dr. Neilson; Dr. James McKenty and Dr. James Pullar have been appointed assistant demonstrators of anatomy. Dr. W. L. Watt will conduct the practical and physiological chemistry.

GENERAL.

Prof. von Mikulicz on America—In lecturing recently at Breslau, Professor von Mikulicz spoke of his recent trip to the United States. He praised American surgeons and said he found more fruitful ideas among them than among the French or English. Part of the allusion was as follows: "The time is past when we were the givers and the Americans the receivers. The American character has as a fundamental feature unlimited self-confidence. The American believes he can do anything that is wanted, and he wishes to see America regarded as the most beautiful and most preeminent land in the world. Nevertheless, we have no ground for fear, for, in the sharp economic contest, the Germans have some advantages over the Americans. The latter recognize the efficiency of the Germans, calling them the 'Yankees of Europe.'"

Drunkenness Among English Women.—In the last report of the London County Council, regarding drunkenness in London, it is stated that of 90 persons taken into custody for habitual drunkenness 89 were women. Whatever these remarkable statistics may indicate, it is certain that they do not represent the proportion of habitual drunkenness in the two sexes. While moral degradation of any sort is more complete and hopeless in women than in men, it is a matter of common observation that the latter furnish the majority of cases of alcoholic and drug excess.

Alcohol is Depopulating Normandy.—The population of the five departments of Normandy is 150,000 less than it was thirty years ago, and the decrease is attributed wholly to the excessive use of alcohol. M. Debove, the dean of the Paris Faculty of Medicine, shows how alcohol operates in two directions toward the diminution of the population—by raising the average of mortality and by weakening the vitality of the majority that survive. There are places in Normandy where the consumption of brandy is more than a quart per day per head of the adult population. Alcoholism is said to have got a firm hold on a large part of the female population. In the "fairly temperate" canton of Tourove the average weekly consumption of raw spirits is a little over three and a half quarts for each male adult and about two quarts for grown up women and young children.

Liverpool Institute of Comparative Pathology—The London *Times*, according to *Science*, states that in connection with the Liverpool Institute of Comparative Pathology (Liverpool University), of which Professors Boyce and Sherrington are directors, a tropical veterinary department has been established. Its objects are to train veterinary and medical men in the tropical diseases of animals, to afford facilities for research in such diseases and organize expeditions, and to organize preventive measures in the tropics against diseases of animals. A memorandum on the subject has just been issued by the institute. It is pointed out that the advantages which Liverpool possesses for the study of tropical medicine are equally applicable to tropical veterinary medicine, there being an immense foreign cattle trade with the port. The Johnston Laboratory of Liverpool University, opened last May by Mr. Walter Long, M.P., contains the fully equipped laboratories of the Institute of Comparative Pathology, of the Tropical School of Bio-Chemistry and of the Cancer Research Committee, and is directly connected with the departments of bacteriology, pathology and physiology. These subjects, closely associated in the new Thompson Yates and Johnston Laboratories, it is pointed out, mutually help one another, and thus increase the thoroughness of training and greatly promote the opportunities for research. The secretary of state for war has approved of the course laid down by the institute, and in future officers of the Army Veterinary Department will be sent to Liverpool for their special training, the Army Department paying the fees. The Liverpool School of Tropical Medicine also trains officers sent specially by the government. In connection with the new department it is desired to establish a practical post-graduate class in veterinary medicine, and also a school of veterinary medicine. Firms interested in the cattle trade have subscribed a considerable sum toward the expenses involved, but further funds are needed.

Another Century Old "New Discovery."—From *Science* we clip the following: "A hitherto undescribed visual phenomenon.—To the Editor of *Science:* The phenomenon of apparent movement described by Dr. Geo. M. Gould, of Philadelphia (*Science*, XVIII, 536), was discussed in 1896 by Professor S. Exner in an article entitled 'Ueber autokinetische Empfindungen' (*Zeits. f. Psych. u. Physiol. d. Sinnesorgane*, XII, 313). According to Exner, the first observation on record was made by Alexander von Humboldt in 1799. Several authors (among them men as well known as Aubert and Charpentier) have occupied themselves with the phenomenon, and it forms the subject of an experiment in Sandford's *Laboratory Course*, 1898, 109.—E. B. Titchener."

New Jersey State Medical Regulations.—Dr. John V. Shoemaker comes out in an editorial in the November number of his *Medical Bulletin* denouncing the New Jersey State Board of Medical Examiners for "the erection of a Chinese wall of exclusiveness which shall shut out practitioners from other States from practising

within its borders." It purports to give a truthful statement of facts sustaining this charge, but in reality distorts the facts and misrepresents the medical legislation and policy of New Jersey. The article is the subject of considerable comment and as it unfairly represents the situation in that State Dr. E. L. B. Godfrey, Secretary of the State Board of Medical Examiners of New Jersey, gives the following reply: "The author of the article on 'Reactionary Measures in New Jersey,' published in the *Medical Bulletin*, of Philadelphia, edited by Dr. Shoemaker, of the Medico-Chirurgical College, is not familiar with the medical statute nor with the rules and regulations governing the licensing of physicians by the State of New Jersey. No legally qualified physician of another State is debarred from visiting patients in this State, provided he does not open an office or put up a sign. No graduated physician is debarred from taking the State examination for medical license, provided he can meet the requirements of the State. No physician is debarred by the State of New Jersey from obtaining an indorsement of a certificate of license issued to him, after examination, by another State, provided the standard of academic, medical and examining requirements of that State is substantially the same as that of New Jersey; and provided further that the candidate for license complies with the same conditions as are required from candidates examined by this State. The academic requirements for a State medical license are based upon a diploma issued after four years of study in a high school of this State. A diploma from a chartered school of equal grade, or a certificate of examination for admission to the freshman class of a literary college, will be accepted as equivalent. Candidates not possessing such diplomas may present evidence of their academic education to the State Superintendent of Public Instruction at Trenton, who is authorized by the State to determine the equivalent of the high school course and to issue certificates which admit to the State examination or indorsement. Full credit is given for any literary, scientific or commercial branches candidates may have studied. Failing to possess the required credentials, candidates may be examined by the State of County Boards of Examiners for Teachers. The Medical requirements are four courses of lectures of at least seven months each, in four different calendar years, prior to graduation from a legally incorporated college. The subjects of examination are the same as they have been since 1894 and consist of fourteen branches of medicine and surgery.

"New Jersey does not prevent any physician from locating to practice medicine in this State who can meet the educational and moral requirements of the State. New Jersey has been one of the most progressive States in the matter of indorsement and has, at this time, reciprocal relations with probably as many States as any State in the Union. The author of the article referred to appears to be a Pennsylvania physician and in his complaint that New Jersey will not indorse a Pennsylvania license forgot to state that Pennsylvania does not indorse the New Jersey license. He demands as a right from New Jersey a courtesy which Pennsylvania does not grant in return. Pennsylvania denied this courtesy to New Jersey when the standards of the two States were equal. Now that our educational standards have been raised to a par with those of New York, the Pennsylvania standards remaining the same, that State cannot reasonably expect indorsement, neither has New Jersey the legal right to grant it. The medical statute of New Jersey is surpassed by none in this country. It is based upon extensive study of the subject, as presented by the States of Massachussets, New York, Ohio, Indiana, Illinois and other States, and was framed by those who have had long experience in State medical examinations. It has the approval of the Medical Society of New Jersey and of the Homeopathic State Medical Society and has been sustained by the Court of Errors and Appeals. Similar statutes govern the practice of law, dentistry and pharmacy. The statute instituting State medical examination was enacted in 1890. It has done more to build up the educational standards of the medical profession of New Jersey than any enactment since the incorporation of the State Medical Society in 1790. At the present time, the proportion of physicians in New Jersey is about 1 to 600 of the population. The demand of the people in these progressive times is not for more physicans but for better educated ones."

Obituary.—Dr. S. S. Lathrop, of Norwich, Conn., thirty-nine years old, was instantly killed Nov. 8, as the result of a collision with an automobile.

CORRESPONDENCE.

MINING AS A SPECULATION.

To the Editor of the MEDICAL NEWS.

Sir: I cannot refrain from expressing my appreciation of your special article on "Speculative Investments for Physicians," in the current issue of the NEWS. As a physician who has lived in Colorado for nearly 10 years I have no hesitation in saying that it is almost impossible for one here in the center of the mining industry to get back his principal if he invests in any form of mining. Appreciative patients often give their physicians absolutely disinterested advice, yet, in spite of this investments almost invariably result in loss. Fortunes are made in mining in States like Colorado, but they are made by the men whose training fits them for practical mining work. Where one physician wins, hundreds are sure to lose, and the first advice which we are apt to give to brother practitioners who come from other States is to scrupulously avoid speculative investments. We can no more play the promoter's game successfully than he can come into our offices and conduct our work. The best a physician can do with his savings, be they small or large, is to put them in a good savings-bank or a good first mortgage bond and be content with a low rate of interest.

While talking about investments, those of us who live in the West might refer to such concerns as the United States Steel Corporation, but that is "another story." PHYSICIAN.

Denver, Colo., Nov. 6, 1903.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, June 4, 1903.

The President, Dr. John M. Fisher, in the Chair.

Placenta Previa and Its Treatment with Especial Reference to Combined Version.—This paper was read by Dr. Daniel Longaker, who said that the report included 17 cases, all of which were seen by the reporter and all but two treated by him. There was but one maternal death, the last he had treated. In this case as well as in the others, combined version was elected. The placenta was completely over the os; labor at term; moderate bleeding; child presenting tranversely. The patient was a multipara, and since reading the paper it was learned that she had committed an abortion on herself about a year earlier. The infant was born by the woman's unaided efforts, after version, in forty-five minutes. There was no bleeding

and none until the manual removal of the placenta, which was markedly adherent. After this moderate oozing continued in spite of an intra-uterine gauze pack; death occurring in three hours. Combined version yielded the most brilliant results in the earlier cases, from the earliest period of fetal viability to the thirty-sixth week and it acted as a most certain means of controlling hemorrhage and of exciting labor pains. It was a certain means of inducing labor. The operation is easy; and the small baby stands compression better than the large one. At least in six of the 11 cases was the baby born alive, and only 8 of the entire 18 were saved. (There was a case of twins.) In every one of the cases of combined turning at or near term the baby was lost. The operation of internal version afforded no better results and was mentioned only to be condemned. One case, a short head first labor, with dead baby, illustrated the inherent dangers of the situation for the child. The method of combined version is believed to be free from danger if the rules laid down by all authorities from the time of Hicks be followed. The most important are to introduce one or two fingers; turn, and wait. The waiting does not mean added risk to the child in the author's opinion and experience. It would be more rational to pay as little attention to the fetus in placenta previa as in ectopic pregnancy; then the warning hemorrhage would be the signal for active aggressive interference, and many cases would be safely disposed of in the later months by combined version. Some of those reaching term would be disposed of by the same plan; others by gradual mechanical dilatation, rupture of membranes, and forceps. All, however, would be actively treated in realization of the fact that the woman's safety lies in evacuation of the uterus. The danger from hemorrhage would be greatly lessened; but there still would remain the remoter ones of septicemia, an embolism and rupture of the uterus, to all of which complications the peculiar conditions predispose. There would remain a small maternal mortality. Of the 17 cases reported, in 10 the placenta was centrally implanted, in 6 marginal, and in one not given. Combined version was employed in 12 instances, internal version in three and in two cases the membranes were ruptured and forceps applied. There was only one maternal death and 10 fetal.

Dr. E. E. Montgomery, said in the discussion, that he was greatly interested in the papers read, and that although these cases covered a period of a number of years, some of them having been delivered before the methods he emphasizes were particularly advocated, it is evident that the management of these cases is excellent. When one comes to look at the side of the mother, the record as made leaves little to be desired. One must, however, keep in mind that in this class of patients the interests of two individuals must be considered. The best record that has been made under this plan of procedure has been pretty close to 55 per cent. mortality for the child. It was his privilege to read a paper before the Philadelphia County Medical Society in 1883 upon the subject, "Is Craniotomy Justifiable for the Living Child?" In this he took the ground that it was not. Following the same line of thought it occurs to him that any plan of treatment which affords a mortality of 55 per cent. for the child, is one which should lead its practitioners to consider earnestly whether there were not other measures that afforded but little increased danger for the mother, and greatly increased opportunities for the child. The plan of procedure he has in view is that of Cæsarean section. He appreciates the fact that it requires a considerable amount of moral courage to urge upon a patient, who is certain for an opportunity for delivery with a mortality of one per cent., the necessity of an abdominal incision with its well-known perils, for the sake of her child. There are many cases, however, in which the birth of the living child is of very great importance to the parents, and in which they are willing to take great chances, and it seemed to him it would be the better part of the obstetrician in every case where the symptoms indicate the presence of a placenta previa to make known the dangers and possibilities that might be afforded for their escape for the child through some operative interference. The hemorrhage in these cases gives an indication of the character of the trouble, and enables the physician to prepare himself to perform the operation under careful aseptic precautions. He is able to choose the time when the operation should be done. There are cases, especially those in which the cervix is rigid, where dilatation is likely to be slow and difficult, that Cæsarean section would afford an increased advantage for the mother. In the performance of the operation it is important that the patient should not have been subjected to careless manipulation or examination previously. The plan of procedure which he had opportunity to practise, in a few instances, during the time he did obstetrical work, is that which affords an excellent opportunity for the life of the mother, the Braxton-Hicks method of version, which has been so well described. It is, however, in those cases in which the placenta covers a good portion of the uterine orifice, a procedure exceedingly dangerous to the child.

Dr. Stricker Coles said: Dr. Longaker's mortality is about 5 per cent. for the mother, and about 50 per cent. for the child. He has in that, of course, some cases of central placenta previa, and that should go to this credit, because that is given as the mortality of the lateral varieties. When one comes to the central placenta previa, Truesdale gives a maternal mortality of about 18.9 per cent., and a fetal mortality of about 70 per cent. He has collected from a large number of cases and has had the best mortality statistics he has been able to see. These figures give an idea of the danger of this condition. Many of these cases come to the obstetrician late, and when hemorrhage has occurred he does not think one can expect to save the child. After a woman has bled until she is almost pulseless and exsanguinated, the chances for a living child are very slight. Two cases have come to him lately in which the child was nearly seven months, and in each case he performed version and used the foot simply as a plug, trying to get the patient to react. In one case delivery occurred in twelve hours; in the other, in six. Both mothers made good recoveries. In such cases one cannot expect to save the child. In cases when the child is not very large, it can often be saved by the method of version, and by taking more time than one would when the child is larger. The cases in which the child is large, the patient having gone nearly to the full term of gestation, he thinks are much more difficult to treat. Version and slow extraction will lose a great many children, but if the children are hurriedly extracted the maternal mortality is increased. With Cæsarean section one has a mortality in the last five years of about 5 per cent. What would be the mortality of Cæsarean section if we could get the cases in the early stage. Control hemorrhage for a short time by packing with iodoform gauze until ready for operation. He thinks there is a field in some of these well-advanced cases of pregnancy with central placenta previa for Cæsarean section, and will expect to see the mortality for mother and child reduced, especially when these cases are placed in a hospital early, or preparation made for prompt treatment at their homes.

Dr. Oliver Hopkinson, Jr., said he thought every case of placenta previa is a law unto itself, and the best results will follow careful study of each case. The advantages of the different operations depend greatly upon the variety of placenta previa. The safest plan, he thinks, is by the old Braxton-Hicks method—dilatation just large enough to admit grasping of the foot. His habit is to grasp the anterior foot, if possible, and after extraction, use it as a tampon, either allowing the labor to end spontaneously or use it as a plug, if there be an excess of hemorrhage. He thinks that method the safest for the mother. He believes the lives of the mother and child in placenta previa are antagonistic, and, in trying to save both, you are likely to lose the mother. If the fetal heart is heard, and the mother is in good condition, he thinks Cæsarean section would be the operation par excellence.

Dr. George M. Boyd said he thought the paper brought out the necessity of carefully studying all cases of ante-partum hemorrhage, and impressed upon the profession the necessity for careful diagnosis in ante-partum hemorrhage, for the early diagnosis will mean often the successful treatment. The treatment in his opinion will depend upon whether one gets the case early or late. If the patient has bled profusely and the pulse is rapid there is nothing to do but podalic version as a method of tamponing the cervix or plugging the uterus and emptying it. In central placenta previa, if the diagnosis is made early, if the child is viable and the patient in good condition, the physician does not do his full duty unless he tells his patient of the danger, the high mortality to the child and gives her the privilege of selecting between the two methods of treatment, podalic version or Cæsarean section. His course has been slow delivery after having accomplished version. He agrees with those who state that rapid delivery means a higher mortality for the mother.

Dr. George Erety Shoemaker said that Dr. Longaker is to be congratulated on the results which he is able to present, considering the class of cases which he has had to deal with and the conditions surrounding them. They were not in maternity hospitals, but were taken as they came, often in poor condition from hemorrhage, under poor surroundings, and his results are excellent. The question as to whether version is the best method of handling placenta previa depends on just that point. Is there any other method known which could take the 18 cases just as they stood at the time they came to Dr. Longaker and yield him a mortality as low as that which he has given? Dr. Shoemaker thinks the answer must be that there is no other method Tamponing and forceps and Cæsarean section certainly would give a larger mortality both for mother and child. As to Cæsarean section, it seems to him that that is a procedure which can only be considered in a very few selected cases seen and diagnosed early, under good circumstances, and where for some extraordinary reason the life of the child is of such importance that it can offset the increased danger to the mother. Cæsarean section even in the hands of the most expert has not yet reached the state where the maternal mortality is as low as in the average delivery by podalic version.

Dr. I. P. Strittmatter said that from his observation in 2,100 obstetrical cases he has seen five of placenta previa, one of complete placenta previa in which the placenta was adherent over the internal os and four cases of partial or marginal placenta previa. The method which he has pursued, and which he thinks he would pursue again under similar circumstances, has been to make an examination as soon as hemorrhage appears. If the os is not sufficiently dilated, it should be dilated enough to see what is the matter. Having determined this, the portion of placenta contiguous to the internal os should be detached, the os packed with iodoform gauze and then the case should be studied. It is hard sometimes to determine the proper course, especially when the surroundings for operations are unfavorable. In one case of placenta previa hemorrhage occurred five weeks before delivery. It was a slight hemorrhage, but it was very easy to make a diagnosis. By packing the cervix with iodoform gauze, allowing it to remain for seventy two hours, washing out and repacking there was no recurrence of the hemorrhage until the time of delivery at 8½ months. The placenta was not perforated. The foot was seized and the delivery accomplished, using the child as a tampon, with a favorable result for both mother and child. In partial placenta previa packing with iodoform gauze and watching the case has yielded good results. In three cases podalic version was performed with recovery to mother and child. In the fifth case the child was delivered with forceps. This case was very interesting, because it was impossible to keep the packing in its proper place by the ordinary methods and it had to be held in position to dilate the os for the use of the forceps. The hemorrhage was slight in the beginning, but it did not recur after sufficient dilatation had taken place to allow the occiput to enter the external os. Personally, he is in favor of podalic version in every instance when there is slow dilatation of the os or inability to control hemorrhage by packing with iodoform gauze. When the hemorrhage can be controlled he thinks it is better to wait for a time, particularly so, if there has been severe hemorrhage. The early diagnosis in placenta previa is everything, and every patient applying for obstetric service, in the presence of any hemorrhage, should be carefully examined and her case carefully studied. If this examination does not yield a decisive result as to the cause of hemorrhage, it should be repeated until a result can be obtained. This offers the best chance of a successful outcome of the case.

Dr. John W. West said that his treatment of placenta previa has been podalic version in every case.

Dr. Richard C. Norris said that no plan of treatment suitable to all cases could be selected. There are three main conditions which would determine the course of action in any given case: The state of the cervix, the degree of hemorrhage, and the variety of the placenta previa. It is well known to those who have had experience with these cases, that where lateral or marginal placenta previa occurs the hemorrhage may be slight; often indeed, not recognized unless the physician studies the attachment of the amnion to the placenta after it has been delivered. The lower uterine segment, thinned, overstretched and edematous, is readily torn and severe lacerations and hemorrhage can follow the speed that one would use ordinarily in extracting. There will be some cases even after version in which the hemorrhage may not be entirely controlled, and here it is well to remember that by slight and steady traction on the foot the hemorrhage can be controlled without injury to the cervix. When one considers the maternal and fetal mortality of placenta previa and determines to try Cæsarean section to improve it, one must remember the unfavorable conditions. The majority of cases are premature births. We have to deal with a premature child and with a child that is more or less exsanguinated. The infant mortality is and always will be great, despite the more rapid delivery. These cases are not ideal cases for surgical interference. He predicts that as time goes on, Cæsarean section will pass away as a means of treatment for placenta previa, and that more and more will we depend upon version and slow extraction, as heretofore outlined. He would lay stress upon the dangers of the third stage of labor in these cases, the hemorrhage fol-

lowing the birth of the child. No one should attend a case of placenta previa without having at hand the appliances to treat this alarming condition. The insertion of a utero-vaginal tampon from the fundus to the vulva, kept in place for twenty-four hours, and gradually removed, is the only treatment. To attempt to stitch any lacerations, is a loss of valuable time. In conclusion, he said that from his experience and knowledge of the experience of obstetricians throughout the world, Hicks has done more to reduce the mortality of placenta previa than has been accomplished by any other treatment, and that placenta previa can never be practically treated by Cæsarean section.

Dr. Charles P. Noble said that his own experience leads him to take that ground most decidedly. While he has not had a large experience, he has had the happy fortune of seeing all the mothers recover. Two cases in which he was consulted, ended fatally because version was not done promptly. The patients bled to death before version was attempted. Aside from these personal results, he thinks the statistics of the treatment of placenta previa in general, bear out the belief that the Braxton-Hicks method of version gives us the best results.

Dr. Longaker, in closing, remarked that the practical difficulties that present themselves to his mind in consideration of Cæsarean section have been so fully answered by Dr. Norris that there remains nothing for him to say. Dr. Hopkinson asks a question about the hand used. Dr. Longaker has never ceased to be thankful to one of his teachers, Dr. Penrose, for the very emphatic way in which he impressed that point upon our minds in his lectures. He would say, "Use that hand which, when held between pronation and supination, the palm corresponds to the child's abdominal surface." It is a very good rule, and he follows it in doing internal version. Version is usually feasible by the combined method. The head is easily displaced. The shoulders come into contact with the intrauterine finger, the other hand depresses the breach, and the knee and foot drop into the intrauterine finger's reach. An assistant or an intelligent nurse can often render useful assistance by making pressure upon the fundus.

Exhibition of Specimens.—Dr. W. Reynolds Wilson exhibited this case. It was one in which the performance of Cæsarean section, followed by hysterectomy, was necessary on account of multiple fibromyoma of the uterus. The indications were perfectly outlined; the obstruction to the passage of the child was absolute, inasmuch as the pelvic cavity was completely filled with a pedunculated tumor. The cervix was pushed forward, and was entirely out the axis of the pelvic canal. It is unusual to find the indications for the operation so clear. In the majority of primiparous women the question of Cæsarean section is based entirely on measurements. This in some instances is indefinite. The woman, a primipara, had reached the beginning of the ninth month of pregnancy. The condition of the kidneys made it necessary to terminate pregnancy at once. There was acute nephritis with blood and granular casts in the urine. The child (weighing 5½ pounds) was rapidly delivered with the uterus *in situ*. Dr. W. Reynolds Wilson found it impossible to deliver the mass from the abdominal cavity before extracting the child, because the pelvic tumor was so great that he could not carry his hand back through the ample incision sufficiently deep to draw out the impacted tumor from the pelvis while the child was still in the uterus. The uterine incision was made at a point on the anterior wall, between the subperitoneal tumors which studded the uterine surface. The amount of hemorrhage was not excessive. The bleeding was constant, but it arose from the delay in reaching the mass in the pelvis, and in getting the tumor completely out of the incision in order that ligation could take place. The adhesions were moderate, so that the operation in this respect was ideal. The mother and child are both in good condition. The uterine tumor weighed seven pounds.

NORTH BRANCH OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting held Thursday, Sept. 11, 1903.

Dr. H. Brooker Mills, in the Chair.

Funic Pulsations—When to Ligate the Cord.—This paper was read by Dr. William Harmar Good. He said that the question was, Are the funic pulsations fetal or maternal in origin? In answer to this question one case was reported where, in a six months' miscarriage, the cord pulsated five minutes after the whole contents of the uterus—child, placenta and membranes intact had been expelled. In another case a ligature was placed around the cord, the pulsation on the placenta side immediately ceased, while those on the fetal side continued for some time. As the pulsations are fetal in origin in a case with a relaxed uterus and a child forcing a lot of blood into a sponge-like placenta, one should not wait for cessation of pulsation before ligating the cord, but, as Caviglia has pointed out, ligate the cord during the first firm contraction of the uterus when the blood is forced out of the placenta into the child.

Dr. A. Bern Hirsh felt that the pulsation originated from the mother, at least to a very large extent. He did not believe that hemostats or ligatures should be applied to the child immediately after birth, but that the cord should be severed before the application of either. He also felt that resuscitation had been aided in many cases by allowing some bleeding.

Dr. Samuel Wolfe felt that as there was no direct communication between the maternal and the fetal circulation, the pulsation must necessarily emanate from the fetus. In reference to tying the cord, he believed that there should be a fair amount of weakening of the funic circulation before it is tied, and if no contractions occur, did not believe tying was necessary. He did not believe bleeding should be permitted, unless there was some indication, such as asphyxiation, therefor.

Dr. Good, in closing, felt that the fact that the pulsations were fetal and not maternal could be demonstrated by observing whether the pulsations were synchronous with the maternal or the fetal heart, and also by the fact that if a hemostat was placed on the cord, the pulsation would cease on the maternal side, but continue on the fetal. He believed that the cord should be ligated in healthy children at once, but that in weak children it is better to wait.

"Syphilitic Pharyngeal Abscess with Necrosis of the Cervical Vertebræ."—Dr. Nathan G. Ward, of Philadelphia, called attention to the fact that syphilis of the upper respiratory tract might occur during any of the three clinical stages of the disease, and may be merely inflammatory, with or without ulceration, or there may be excessive necrosis, the most distinctive and intractable lesions occurring in the tertiary stages, and postpharyngeal abscesses with necrosis of the cervical vertebræ being rare. He reviewed the work of Allin, who in 58 cases of postpharyngeal abscess, four of which were complicated by cervical necrosis of syphilitic origin, and also the cases reported by Mackenzie and Chapman. He then reported a case which occurred about three weeks after the last confinement which occurred about twelve years ago; the first manifestations

of the disease appearing on the genitalia, followed six weeks later by erythematous, papular and vesicular eruption over the entire body, later disappearing, after which she was free from trouble for some time, when ulcerations appeared on the anterior surfaces of both legs below the knee; one over the left malar bone, and a severe iritis with synechiæ. When first seen by the writer, September 25, 1898, these lesions had all healed but there were three ulcers on the right shoulder and one on the posterior wall of the pharynx about three-quarters of an inch in diameter surrounded by soft pulpy granulations and covered with yellow, foul smelling pus, which continually oozed from the sinus at the bottom of the ulcer. A probe passed down the sinus to the cervical vertebræ showed it to be hard and resistent, with no rough or necrosed areas. She had been unable to lie down for six months, and the pain was so intense that very little sleep was obtained in a Morris chair, which was worse at night and in damp, stormy weather, it being necessary whenever she moved to steady her head with both hands. The ulcer was cleansed daily with peroxide of hydrogen and the granulations touched twice a week with chromic acid. Her history revealing the fact that iodides and mercury had already been given to the point of tolerance, the following was given in teaspoonful doses three times a day:

R Iodixe
Bromine, aa..... gr. ⅙
Phosphorus .....gr. 1/100
Sherry, q.s.....dram 1

In addition, phosphate of sodium and calomel were given to prevent constipation. K. I. was attempted to be administered without the patient's knowledge, but each time she detected its presence and complained of pain and nausea. In about three weeks the ulcer looked healthier and soon after broke down and was as bad as at the beginning. About the middle of November a small piece of bone was seen protruding in the sinus, which could be manipulated slightly, but was not entirely free, and moving it caused much pain. By gently moving it at each visit, in one month it was entirely free and a piece of bone one inch by three-quarters of an inch was removed, which was full of holes. Again the ulcer underwent a course of healing and growing worse and in March of that year another piece of bone was removed one-half inch square, after which the ulcer healed and has remained so during the period of four years following it, and there have been no symptoms.

Dr. Carle Lee Felt stated that he believed a long time was required to completely eradicate the syphilitic poison from the system, and that many of the cases recurred in some form after being pronounced cured, reporting a case which had been discharged as cured followed a month later by syphilitic gumma obstructing the nose. He reported another case in which the patient was suffering from a thickened nasal wall, and although he absolutely denied specific infection, the condition was cured by the use of K. I. In reference to the Wine of Iodide, he stated that he employed it with benefit in a case in which K. I. could not be tolerated.

Dr. Lewis S. Somers felt that syphilis was one of the most complicated diseases involving the walls of the pharynx, the posterior wall being usually affected. He believed that no matter what treatment was used, the disease was liable to reappear for three or four years, and referred to the case of a man where there were local manifestations twenty-five years after the discontinuance of treatment.

Dr. J. Cardeen Cooper felt that Wine of Iodide was especially valuable because it improved the patients' general condition, as the stomach is frequently in a condition where it will not tolerate either food or medicine. He remarked the fact that women usually improve more rapidly than men, which he attributed to the fact that they did not smoke, as the improvement was also more marked in men who were non-smokers. He did not believe that syphilis was an incurable disease, and felt that in those cases which were reported as showing no manifestations for twenty-five years, the symptoms had been present, but were so slight that they had been overlooked.

Dr. Ward, in closing, stated that he had seen two cases of gumma of the posterior wall of the pharynx, and called for the necessity of promptly arresting the progress of the disease in order to prevent the destruction of tissues. He stated that he had received marked good by inhalation of tincture of iodine in the form of a vapor, using the water as hot as it can be borne.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

SECTION ON CLINICAL MEDICINE AND SURGERY.

Stated Meeting, held Friday, October 16, 1903.

Election of Officers.—John B. Blake, M.D., was elected President; Dr. Macgruder, Secretary, and Dr. Ruhrah, junior, member of the Executive Committee for the ensuing year.

Sarcoma of the Nasal Septum. Exhibition of Case and Pathological Specimen.—Dr. R. H. Johnston presented this subject. The patient is a woman aged 70 years. Her mother died at 78 years of an abdominal tumor which was diagnosed a cyst and had originated two years previously. One sister died from a growth in the left side of the neck. The patient has lived an active life as a nurse since 1861. Her health has been good since childhood until two years ago, when she had an attack of pneumonia. In December, while nursing, she contracted a "cold in the head." Home remedies were applied without effect and in February a swelling appeared on the left shoulder followed by involvement of the pre-auricular glands. At this time her physician found a nasal obstruction, but the glands were diagnosed as tuberculous. Three weeks ago the patient came to the Presbyterian Hospital of this city. The left side of the nose was swollen, the pre-auricular and cervical glands were enlarged as well as those above the clavicle. The patient complained of complete nasal obstruction and asthmatic attacks, but there was no pain or hemorrhage. Examination showed a deviation of the septum on the right side with complete obstruction of the nasal passage. On the left side there was a pink, hard, non-movable swelling which was attached to the septum, bled easily and closed the nasal passage. Under the microscope the section of the tumor showed that it was largely cellular with little connective tissue and the diagnosis of sarcoma was made. The tumor was inoperable but portions of it were removed in order to increase the patient's breathing space. The opening, however, closed as fast as it was made. The glands are continually growing and are becoming tender. Dyspnea and dysphagia are now present and enlarged glands are palpable in the axilla. Sarcomata of the nose are rare, Kümmel being able to collect only 69 cases in the literature. The inguinal glands in this case are not enlarged, but the patient complains of some abdominal tightness pointing possibly to involvement of the liver. The question was raised whether this case had any connection with Hodgkins' disease. Microscopically the

tumor is a lymphosarcoma, and it is important to know whether the symptoms of nasal obstruction or the glandular enlargement appeared first. Dr. Johnston stated that the patient is certain the nasal obstruction appeared before the glands.

Creeping Eruption.—Dr. Hamburger said that this disease was unrecorded in America until September, 1902. Patient was an imbecile boy of four years. His history could not be obtained. Examination showed a linear eruption about the center of the buttock running vertically and about 1½ mm. wide. It was pale red, raised and surmounted above by vesicles. The lower portion consisted of purplish brown pigmentation surrounded with crusts. The lesion was migrating slowly, the line advancing about 6 cm. in twenty-four hours. A piece of skin just ahead of the growing end was excised; no parasite was found, but the line immediately faded and has since disappeared. Dr. Lee, of London, showed a case of creeping eruption before the clinical society there in a child three years old. The line migrated 4½ inches in twenty-four hours, taking a very irregular course from the leg across the back and abdomen. It was cured by excision. Crocker calls this disease larva migrans. Several cases of creeping eruption have been observed in Russia, where the disease appears most frequently in the autumn months and shows a black point just ahead of the growth which has been proven to be a larva, similar to that of the fly. None but the Russian cases have shown larvæ, although the symptoms of cases observed elsewhere point to a closely allied, if not indentical, etiology. The disease is prone to affect children and involves generally the uncovered portions of the body, but often the buttock. In Russia the peasants seem to be most often affected. The characteristics are those of an advancing red line with a pigmented area left behind. Vesicles are frequent but pustules never occur. The duration varies from a few days to five weeks. In one of Crocker's cases it lasted 2½ years. The serpiginous course and the absence of suppuration show the diagnosis. The treatment is obvious: Excision of the piece of skin just ahead of the advancing lesion. The larvæ of the bot fly are parasitic to mammals, but the parasitism is limited to one species. Myiasis, or infection with the larvæ of flesh flies, is generally divided into two forms, the internal and external. The intestines, nose, eyes, urethra and vagina may be affected by the disease. In external myiasis the bot flies probably play a part and the larvæ of creeping eruptions belong probably to the bot fly group. The symptoms of cutaneous myiasis seem to vary in different geographical regions. The points of interest in Dr. Hamburger's case are (1) the dermatological features; (2) the question of its relation to myiasis; (3) the fact that it is only the second case described in this country. Dr. Lord also had a case of creeping eruption in his clinic in a Bohemian woman, forty-five years old. The disease lasted four to five weeks. No larva could be found, and it was cured by excision.

The Bicêtre Hospital of Paris.—Dr. Emerson discoursed on this subject. The Bicêtre Hospital is an insane asylum and almshouse for men as the Salpetriere is for women. It has a beautiful situation and an interesting history. It was founded in the thirteenth century by the Bishop of Winchester as a settlement on his estate. In 1657 Louis XIV. established an asylum and almshouse for retired soldiers, luetics, children of dissolute parents and other unfortunates and the hospital has since had great historical interest. The first school for imbeciles was established here and Pinel introduced humanitarian treatment at this hospital, and not at the Salpetriere, as is commonly supposed. Broca also had his training there. The hospital has about 3,500 inmates, gathered from the poor, the insane and the idiotic children of Paris. The city spends on it about $400,000 a year. The treatment is good and the poor of Paris desire to be admitted to the hospital. There is a splendid insane department, a fine school for idiotic children under Borneville, and the wealth of material for neurological students is tremendous. Marie has charge of these cases and their number and value may be judged from a few statistics. The first case of ascending peripheral neuritis, now called syringomyelia, was reported from this clinic; so, of the first case of double athetosis, now known to be chronic chorea. Here, too, are the original cases of cerebellar ataxia and syringomyelia of the ataxic type. Marie, while studying hemiplegia from the standpoint of the palatal reflex, collected 50 right-handed cases and 50 left-handed cases and in another investigation gathered together 20 cases of syringomyelia, a disease considered a rarity elsewhere. The abundance of material may be further estimated from the fact that one autopsy is made a day and only the nervous system of the subject is examined. Marie actually finds more cases of combined sclerosis than he can follow. Paris affords a splendid chance for one who knows just what he wants and needs material for study.

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.*

The President, Dr. Samuel J. Meltzer, in the Chair.

The third regular meeting of the Society for Experimental Biology and Medicine was held in the lecture room of the Department of Zoology, in Schermerhorn Hall at Columbia University, on Wednesday evening, October 21.

The following reports† and demonstrations of original investigations were made:

An Experimental Study of Cell Specification in Embryonic Development.—Prof. Edmund B. Wilson presented the results of a study of the development of isolated embryonic cells, in the mollusks *Patella* and *Dentalium*, which demonstrates that from the first cleavage onward an isolated blastomere undergoes essentially the same differentiation as if it had remained in connection with its fellows. These eggs accordingly show a true mosaic-development, and differ widely in this respect from those of echinoderms. It was also shown that the specific character of the cleavage-cells is predetermined, at least in part, by specification of the regions of the unsegmented egg from which the blastomeres arise, as is proved by the development of fragments obtained by cutting the egg in two before development has begun.

The Occasional Presence in the Blood of Untreated Adult Animals of Large Amounts of Substances Agglutinating Many Bacteria, With Demonstrations.—Dr. William H. Park said that the affinities of bacteria for specific agglutinins have, since the researches of Gruber, been made use of to establish relationship between different cultures. The test properly performed is delicate and reliable, but when carried out with insufficient precautions is often misleading. It has been known for some time that the blood of animals before immunization possessed, in moderate amount, substances which agglutinated many bacteria. An agglutination of bacteria must, therefore, take place

*From American Medicine.

†The abstracts here given have been prepared by the authors themselves. The Secretary has made only a few abbreviations and minor changes.

in a high dilution of serum before it can be considered a specific reaction. From results obtained in his own researches Dr. Park considers that even this requirement is insufficient. He found that before any inoculations had been made the blood serum of certain horses agglutinated, even in such great dilutions as 1 in 1,000, both the bacilli having the characteristics of the true dysentery bacilli of Shiga and those having the characteristics of the mannite-fermenting class of Kruse, Flexner, and Duval. This was true to a somewhat less extent of the serum of full-grown goats. It has happened in some instances that after repeated injections with cultures of one of the varieties of the dysentery bacilli, the animal's blood agglutinated the variety of bacilli not used in immunization in as great or even greater dilutions than it did the variety injected.

It was found that a serum drawn from a horse which had been immunized by repeated injections of the dysentery bacillus received from Shiga, agglutinated this bacillus in dilutions of 1 in 500. The same serum, however, agglutinated the mannite-fermenting bacillus in dilutions of 1 in 1,000. The serum from another horse which had received injections of the mannite-fermenting bacillus, agglutinated this bacillus in dilutions of 1 in 1,000, but also agglutinated the Shiga bacillus in dilutions of 1 in 500. Judged by these reactions, these two varieties of bacilli would appear to be much alike in their affinities. Indeed, Shiga and Flexner seem to have come to this mistaken conclusion. Duval and Bassett certainly fell into this error when they announced, in the fall of 1902, that the mannite-fermenting type from the Baltimore diarrhea cases, and the Shiga type, had identical agglutination characteristics.

The blood of young animals was found by Dr. Park to be comparatively free from bacterial agglutinins. A goat six weeks old was found to possess no appreciable bacteria agglutinating substance in its blood. After four injections of a culture of Shiga dysentery bacilli, its blood in dilutions of 1 in 500 agglutinated Shiga bacilli, but only in dilutions of 1 in 10 the mannite-fermenting variety. A rabbit whose blood was negative before immunization, after six injections of this bacillus agglutinated the mannite-fermenting bacillus in dilutions down to 1 in 5,000. The Shiga bacillus was agglutinated only in dilutions of 1 in 20. The slight development of substances which agglutinated the mannite-fermenting type during the process of immunizing to the Shiga bacillus cannot be considered as showing any affinity between the Shiga type, and the fermenting type, since about the same increase was found in animals injected with nutrient bouillon and other substances.

Gastric Secretion Induced by a Reflex From the Intestine.—The main points in Dr. Holmes C. Jackson's results were summarized by him as follows: (1) The introduction of alcohol into the intestine sets up a reflex which causes the secretion of gastric juice. (2) Section of the nerves which supply the stomach (vagi and sympathetic), or the administration of atropine, prevents this reflex, whereas nicotine has no such effect. (3) Of the substances other than alcohol examined in this connection, it was found that oil of peppermint also induces a reflex secretion, but that other irritants, such as mustard and ether, do not show this action. (4) Section of the nerves, or the administration of atropine or nicotine, followed by the introduction of alcohol directly into the stomach, gave results similar to those obtained when the alcohol was injected into the intestine.

The Organism of Smallpox, With Demonstrations.—Dr. Gary N. Calkins, after briefly describing some of the phases in the complicated life history of the smallpox organism, *Cytoryctes variolæ Guarnieri*, demonstrated twelve stages of the organism stained by an adaptation of the Borrel method whereby the organism stains red upon the green background of cell body and nucleus. A similar parasite, as yet undescribed, in the macronucleus of *Paramœcium caudatum* was also shown.

On Respiratory Stimulants, With Demonstration.—Dr. George B. Wallace demonstrated a method for estimating the volume of expired air. A rabbit was used and the volume of air expired under normal conditions, and after the animal had been given a respiratory stimulant, was measured. The apparatus used was a modification of the one devised by Dreser. In the experiments reported by Dr. Wallace, the greatest increase in respiration occurred after administration of atropine, the amount of expired air being increased 75 per cent. Strychnine produced an increase of 35 per cent., caffeine, 9 per cent.; cocaine, 7 per cent.; aspidospermine and quebrachine (two alkaloids obtained from *Quebracho blanco*), 9 per cent., and 17 per cent., respectively.

The Intracellular Reduction of Gold Chloride, With Demonstration.—Dr. A. N. Richards' experiments were on the effects of intravascular injections of the double chloride of gold and sodium, and were carried out under the direction of Professor Schmiedeberg. Microscopic examination of the tissues of rabbits killed by lethal doses of this salt shows the deposition of metallic gold in and immediately about the nuclei of the cells of the kidney, liver, spleen, mucosa of the gastro-intestinal tract, and cardiac muscle. By chemical analysis, it was found that by far the greatest amounts of gold are deposited in the kidney and liver, only traces having been recovered from the other organs.

On account of the ease of reduction of this salt and the possibility of the accurate estimation of the metallic gold, its use is recommended as an indicator of the *quantitative* relationship of the reducing processes in the various organs.

Effect of Ligation Upon the Vital Staining of Nerves, With Demonstration.—The President, Dr. Samuel J. Meltzer, demonstrated pieces of dried sciatic nerves of rabbits which *intra vitam* received intravenous infusions of methylene blue. Single ligatures of the nerve, no matter where applied, are without any influence upon the color of the nerve on either side of the ligature. When the nerve is ligated at two places, the section between the two ligatures remains free of color, while the central and peripheral ends of the nerve turn blue in the usual manner. The effect is the same even if the ligatures are applied near either end of the nerve. This fact shows that, in the vital staining, the methylene blue reaches the nerve only from its central and peripheral ends.

Effects of Blood-letting on Metabolism.—The Secretary, Dr. William J. Gies, reported the results of some experiments recently conducted by him in collaboration with Dr. P. B. Hawk. The experiments were carried out on dogs in a state of nitrogenous equilibrium. The withdrawals of blood were made while the animals were under the influence of ether-chloroform. The metabolic effects of anesthesia and of operation were carefully controlled. We found that hemorrhages of about three per cent. of the body-weight caused among other effects, (1) diminished secretion, and decreased specific gravity of the urine at first, the reverse in twenty-four to forty-eight hours afterward; (2) increased elimination of nitrogen and sulphur, and decreased excretion of phosphorus, in the urine. The amount and consistency of the feces were unaffected. Repeated hemorrhages from the same animal resulted in (*a*) cumulative quantitative metabolic effects in harmony with those indicated above, and were followed by (*b*) steady decline in body weight and (*c*) gradual increase in average daily

volume of urine, even when the animals ate the same amount and kind of food, as at the beginning.

After successive hemorrhages at intervals of a few days the content of nitrogen, sulphur and phosphorus in the blood, as well as specific gravity and number of red corpuscles, gradually diminished, whereas the leucocytes steadily increased in number. Their data confirm the general metabolic results obtained in the earlier experiments by Bauer and others, and disagree with the opposite conclusions, as to effect on proteid catabolism, announced two years ago by Ascoli and Draghi.

BOOK REVIEWS.

SYPHILIS IN DENTISTRY. By L. BLAKE BALDWIN, Chicago, Professor of Dermatology and Venereal Diseases, Post-Graduate Medical School, and EZRA READ LARNED, M.D., Chicago. E. H. Colegrove, Chicago.

THIS little book of but 120 pages furnishes in brief very useful information as to the possibilities of the contraction of syphilis innocently, and contains valuable information not only for dentists, but for medical men. A good historical account forms the introduction and the work is illustrated by a series of colored plates, sure to form an attractive feature for dentists, since they are not likely to be familiar with the appearance of syphilitic lesions. There is a short but valuable appendix on the medicolegal aspects of syphilis that adds another commendable feature to the volume.

YEAR-BOOK OF THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK, June, 1903.

THIS little book in its 200 pages forms an excellent index of the work that is being accomplished by the youngest of our local medical societies here in New York. The officers and executive committee of the society, Medical Association of the Greater City of New York, certainly deserve to feel proud of having found a place for a medical society and then having filled that place so well. The scientific proceedings as given in brief, form an excellent compendium of the year's work and we commend it to other societies as an example of one way to secure a valuable reminder of the subjects that have been discussed.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Issued Monthly Under the General Editorial Charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol. VII. Pediatrics, Edited by ISAAC A. ABT. M.D. Orthopedic Surgery, Edited by JOHN RIDLON, A.M., M.D., June, 1903. The Year Book Publishers, Chicago.

THESE handy little volumes are making a distinct place for themselves. The review of the literature is excellent and well calculated to keep the general practitioner in touch with medical progress. Advances in medicine are often a source of surprise. Aphthous stomatitis, for instance, has always been in the minds of most practitioners a simple form of infectious disease of the mucous membrane. The review of the literature in the present volume shows its relation to foot and mouth disease. The question of typhoid fever in children is excellently reviewed and shows that this chapter is not, as used to be considered, the analogue of that part of natural history which bears the title, "Snakes in Ireland." Of course, Professor Ridlon's review of orthopedic surgical progress is complete and practical.

GYNECOLOGY. A Text-book for Students and a Guide for Practitioners. By WILLIAM R. PRYOR, M.D., Prof. of Gynecology in the New York Polyclinic Medical School; Attending Gynecologist to the Polyclinic Hospital; Consulting Gynecologist to St. Vincent's Hospital, New York City Hospital, St. Elizabeth's Hospital; 163 illustrations in the text. D. Appleton & Co., New York and London.

IN writing this little manual, the author has tried to avoid all the unnecessary portions of the subject which are not essential for a practical working knowledge of the diseases of women. Special endeavor has been made to have this book valuable as a ready reference to those working in private practice, where time is too often lacking for the reading of the larger and more comprehensive volumes devoted to the subject.

Realizing that the average practitioner is called upon to treat many simple gynecological troubles and that he may be "at sea," most excellent and explicit rules for treatment are to be found in the various chapters devoted to the specially common female complaints.

There is no doubt that the book will serve most satisfactorily the purpose for which it was intended.

DISEASES OF THE EYE. By HENRY R. SWANZEY, A.M., M.B., F.R.C.S.I., Surgeon to the Royal Eye and Ear Hospital and Ophthalmic Surgeon to the Adelaide Hospital, Dublin, etc. Eighth revised edition. With 168 illustrations and zephyr card of Holmgren's tests. P. Blakiston's Son & Co., Philadelphia.

THIS well-known book has been thoroughly revised, and with numerous additions, which bring it well up to date, deserves the approval it has hitherto received. A brief mention of some of the newer features shows that the author is in touch with what is best in modern progress: In Chapter IV, a description of conjunctivitis petrificans; in Chapter VI, a description of grating keratitis, guttate keratitis, etc.; in Chapter VIII, a more detailed account of Kuhnts' method of extirpation of the lacrymal sac; in Chapter X, a more detailed account of sympathetic ophthalmitis. The treatment of this important subject is a model of clearness and conciseness.

Chapter XIV contains an unusually clear description of the use of the Roentgen rays for the discovery of foreign bodies, and of the magnet for their removal.

The portions of the book dealing with the relations of the eye to the nervous system are among the most helpful, in concise form, of the many treatises on this subject within reach of the student.

The conservatism of the author and his admirable style are sufficiently familiar. The book is well indexed. The illustrations are not as numerous as has been the custom in recent works on the eye, and are not especially well executed. This book may be warmly recommended as a practical guide for the student, dealing less with the theory and pathology of the subject than with diagnosis and treatment.

SIGHT AND HEARING IN CHILDREN. By ROBERT BRUDENELL CARTER, F.R.C.S., Consulting Ophthalmic Surgeon to St. George's Hospital, and ARTHUR H. CHEATLE, F.R.C.S., Assistant Aural Surgeon to King's College Hospital; Surgeon to the Royal Ear Hospital, etc. pp. VI+120. The Scientific Press, Limited, London.

THE first part of this admirable little book comprising seventy-five pages is devoted to vision, its mechanism, the causes and consequences of its defects, aids to vision, and the cultivation of vision.

It would not be easy to make the complex subject of

optics as well as the physiology of the eye more clear to the laity than is done in the first chapter.

It is, of course, a question whether many teachers and parents will make even this brief excursion into a land unfortunately too little known, but there should be no chance for ignorance, and we know of no book giving information indispensable to those having charge of the education of children so simply, with such charm and absence of pedantry, as does the one under consideration.

Certain points deserve especial consideration. The importance of having the vision of all children examined at the beginning of school life, and at intervals thereafter; this should be done, the author holds, not only as regards acuteness, but also as regards rapidity of perception. The methods employed in the child's instruction, the amount of work exacted from him in a given time, and perhaps his ultimate destination in life, should all be governed by a complete recognition of the nature and degree of his defect.

Although it is the author's intention to put clearly before the public the causes and consequences of defective sight, there are pages which may be read with profit by the specialist, so full are they of conservative common sense. Fortunately, in this country, educators are aware of the importance of testing the sense perceptions of children, and with characteristic zeal the professional part is being done very thoroughly—perhaps too thoroughly the author thinks, in some particulars, at least.

The importance of exercises, preferably competitive, for the cultivation of vision, and the use of charts, such as those suggested by Dr. Joy Jeffries, for the development of color perception (not, of course, with the hope of influencing or altering the defective sense of the congenitally color-blind) is recommended.

In the remaining 40 pages is compressed a very clear and practical description of the ear, nose and its adjacent parts, with suggestions for their care, such as all having to do with children should be made perfectly familiar with. The prevalence of partial deafness among children will no doubt surprise many non-professional readers, and the importance of its prevention should be impressed upon them. The chapters devoted to the care of the ears in childhood, especially as regards the general health and hygienic surroundings, and to the recognition of diseases of the ear and of the nose, are especially to be commended. No suggestions are made as to treatment, for, as the author wisely says—"Household surgery is always risky unless it is guided by the surgeon's hand, and probably is most dangerous in diseases of the eye and ear."

DISEASES OF THE NOSE AND THROAT. By CHARLES HUNTOON KNIGHT, A.M., M.D., Professor of Laryngology, Cornell University Medical College; Surgeon, Manhattan Eye and Ear Hospital, Throat Department, etc. P. Blakiston's Son & Co., Philadelphia.

A WRITER on this specialty must needs bring medicine and surgery unconsciously into a very close relation, for it is but a short step from spraying the nose to the ablation of hypertrophied tissue in rhinitis, or from the removal of adenoids to the opening of the Eustachian tubes by Politzerization. Many authors are indeed tempted by the technical interest of surgery to magnify the importance of operations and to pay too little attention to non-surgical treatment, a scheme which does not suit the general practitioner who is looking for information which he can apply in his practice. Such a fault can hardly be attributed to the present author, for in his own words "The contents (of this book) have formed the basis of a course of lectures at Cornell University Medical College and are arranged chiefly for the convenience of students." As the student is taught so that he may become a good practitioner, we can think of no arrangement that could better satisfy the physician's needs. The order of subjects is Nose, Pharynx, Tonsils and Larynx. A short chapter on the anatomy and physiology of the parts is followed by one on "Methods of Examination," in which attention is directed to the importance of the much-neglected digital examination of the nasopharynx. The subjects of adenoids and hypertrophied tonsils are most fully treated, the author having no words too strong in condemnation of those who advise to leave children with hypertrophied tonsils to outgrow the condition. The illustrations are good and we commend the book as an excellent working text-book on the subject.

FIRST PRINCIPLES OF OTOLOGY. By ALBERT H. BUCK, M.D., Clinical Professor Diseases of the Ear, College of Physicians and Surgeons, Medical Department of Columbia University; Consulting Aural Surgeon New York Eye and Ear Infirmary and Presbyterian Hospital. Second edition. 216 pp. Wm. Wood & Co., New York.

IN this little book the author shows the power so familiar to his many students, of selecting from an immense experience the essentials of his subject. It puts forth in a clear, concise and accurate manner the fundamental principles of otology. The work is not burdened by various theories, confines itself to established facts, and embodies the personal views of its distinguished author. It well represents the advancement of aural surgery of to-day. The purpose for which it was designed, to meet the need of the student and general practitioner as a ready and practical reference, it meets admirably.

DISEASES OF THE EYE. By CHARLES H. MAY, M.D., Chief of Clinic and Instructor in Ophthalmology, College of Phys. and Surg., N. Y., 1890-1903; Ophthalmic Surgeon to the French Hospital, etc. Third edition, revised. With 275 original illustrations, including 16 plates with 36 colored figures. pp. XIII+408. Wm. Wood & Co., New York.

THE popularity of this book is attested by the rapid succession of editions, and it is a well-deserved success. The author has learned by thirteen years of experience in teaching, what the medical student should know, and what, in the multiplicity of his immediately important duties, may be omitted. The descriptions are terse and clear, and no space is wasted with details of theory or discussion of mooted points.

The appearance of the volume and the excellence of the illustrations, an unusual feature in books of this caliber, are worthy of note.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

ORIGINAL ARTICLES.

EXPERIMENTS TO DETERMINE THE VALUE OF FORMALIN IN INFECTED WOUNDS OF THE EYE.

BY J. H. CLAIBORNE, M.D.,

AND

EDWARD B. COBURN, M.D.,

OF NEW YORK.

THE object of the experiments herein detailed was to discover the value of formalin in the local treatment of streptococcus infection of the ciliary region and the vitreous chamber in rabbits. They were inspired by the recent publication, by Dr. C. C. Barrows, of a case of general streptococcus infection following labor in which formalin, 1 in 5,000, was used as an intravenous injection. These experiments were conducted in the Physiological Laboratory of the College of Physicians and Surgeons, New York.

By way of ascertaining what effect a comparatively strong solution of formalin would have upon the vitreous body, 10 minims of a 1 in 500 solution were injected into a normal vitreous. Outside of the temporary increase of tension and haziness of the cornea produced by the induced glaucoma, no evil effects whatsoever were observed. The glaucomatous symptoms disappeared in about ten minutes and on the following day no sign of the injection was visible. From this it is obvious that formalin in the above strength has no disintegrating effect upon the vitreous of rabbits.

Infection of Rabbits' Eyes.—Colonies of pure streptococci were placed in water in sufficient quantity to make it perceptibly turbid. This was injected into the vitreous of the rabbits' eyes with a hypodermic needle as follows:

January 30, 1903.—I. White buck. Three minims of the solution of pure streptococci were injected into the vitreous behind the sclerocorneal margin. Ten minutes later no signs of reaction were visible in the eye. II. Spotted buck. Three minims of the above solution were injected into the vitreous. No reaction was noticeable in ten minutes. III. White Buck. Injected as above. No immediate reaction.

Results.—January 31.—I. Circumcorneal injection; iris swollen; lymph stretching across the pupil and exudate at bottom of anterior chamber; fundus hazy; mass of exudate in vitreous humor just under site of injection. II. Slight circumcorneal injection; iris swollen; exudate in pupil; faint reaction of iris to light; fundus hazy with flamiform exudate visible in the anterior part of vitreous humor. III. No reaction visible externally; iris clear and responds to light; fundus clear except in region where injection was made where a mass of greyish white exudate is seen.

It is obvious from the above that the injection of streptococci produced uveitis with exudation into the pupil and vitreous humor in the first and second rabbits. This unquestionably was an infection. The third rabbit showed no iritis or corneal injection but there was a slight exudate in the vitreous. The infection here was milder but it existed.

Beginning of Formalin Injections.—February 2.—I. Iritis better and exudate slightly less. No treatment. II. Status about the same as last noted; exudate general in vitreous chamber. Five minims of formalin solution, 1 in 5,000, injected into Tenon's capsule. III. Status about the same as on January 31. Marked exudate in vitreous. Five minims of formalin, 1 in 5,000, injected into vitreous chamber.

February 4.—I. No iritis and the vitreous opacity appeared less marked. In this animal it will be remembered that no injection of formalin was made. II. Iritis much improved; opacity in vitreous slightly diminished; eye better. In this animal the injection was made in Tenon's capsule. III. The iritis appeared diminished but the vitreous was very cloudy and little or no reflex could be seen. Formalin injection was made into the vitreous in this animal.

It will therefore be seen that the eye which was not treated had improved a great deal. The eye which received the injection of formalin in Tenon's capsule was improved somewhat. But the third eye (which had the injection in the vitreous) had improved as to the iritis but the posterior inflammation was worse. On this date, February 4, the injections were repeated in rabbits I and II but discontinued after that date until February 9.

February 9.—I. Still improving; exudate becoming less but still visible. II. No iritis; exudate in vitreous less and apparently settling to bottom of vitreous chamber. III. Exudate still visible; more marked than in rabbit II. Injections were repeated on this date. The eye of rabbit I, which had not been previously infected, was now infected with streptococci as before described.

February 11.—The newly infected eye of rabbit I was in a bad state; purulent conjunctivitis; iritis; cloudy vitreous and fundus invisible, the originally infected eye was still improving. Formalin injections were repeated in rabbits I and II, the status of which was apparently unchanged.

February 13.—Newly infected eye of rabbit I is destroyed by panophthalmitis. Exudate in the original eye almost entirely gone. Rabbit II, the one in which the injection was intracapsular, was much improved; fundus visible and exudate sinking and being gradually absorbed. III. Eye practically in state of panophthalmitis; 1 in 1,000

formalin solution injected. 1 in 1,000 formalin solution was now used in rabbit II into the capsule as usual and in III into the vitreous.

February 16.—I. Right eye improving; exudate scarcely visible. Left eye, fundus invisible but external signs subsiding. II. Still improving; fundus clearly visible except below. Formalin injection 1 in 1,000 in capsule. III. Iris bombé; fundus invisible and reflex yellowish but external signs again subsiding. Injection of 1 in 1,000 formalin into vitreous.

February 18.—I. Right eye almost clear. Left eye destroyed; posterior synechiæ; yellowish reflex in pupil; tension -2; external inflammatory signs such as conjunctivitis and pericorneal injection gone. II. Fundus still clearing up; intracapsular injection of 1 in 1,000 formalin. III. Hyphema; about same picture of destruction as exhibited in left eye of rabbit I. Injections discontinued.

February 20.—I. Right eye shows clear fundus. Left eye destroyed. II. Improving; fundus almost clear. Formalin injection into capsule 1 in 1,000. III. Destroyed.

It will thus be seen that the right eye of rabbit I infected by five minims of a turbid solution of pure streptococci recovered without any treatment whatsoever in twenty-one days.

The fundus in rabbit II finally became clear. This animal infected in the same way recovered in a trifle longer time after injection into the capsule of 1 in 5,000 formalin, subsequently supplemented by injection of 1 in 1,000 formalin.

The eye of rabbit III was obviously doomed on the seventh day and was hopelessly destroyed in fourteen days. On the fourteenth day the formalin was increased to 1 in 1,000, and rabbit II seemed to recover more rapidly thereafter, but it made no difference in the course of destruction of the eye of rabbit III.

The right eye in each case was originally infected but at no time during the three weeks were there any signs of sympathetic irritation or inflammation.

On February 9, the left eye of rabbit I was infected with the same pure culture and that eye went swiftly to destruction.

It will be seen that the eye with the vitreous injection of formalin ran an uninterrupted course to destruction while the eye with the intracapsular injections recovered. This latter fact would have led to definite hopes of good results from capsular injections had it not been for the more rapid recovery of the eye which had no injections at all.

Second Set of Experiments.—Some of the original colonies of streptococci were now transplanted and the strong vigorous growth obtained was used in a second series of experiments. The new colonies seemed to possess greater virulence than the older ones.

The vitreous of three rabbits was infected as before. In one no treatment at all was employed and in the other two formalin solution 1 in 1,000 was injected into the capsule of Tenon. All three eyes commenced to go the way to destruction in twenty-four hours after infection, although formalin injections of the above strength were used in the capsule at intervals of twenty-four hours in one rabbit and forty-eight hours in the other; all the eyes had become hopelessly lost by panophthalmitis by March 25.

Experiments with Infected Wounds of Ciliary Region.—So far the vitreous chamber alone had been infected and it was then determined to make wounds in the ciliary region with some rough object infected with the streptococcus solution of the second growth.

The eyes of two rabbits were infected by making a penetrating wound just behind the sclerocorneal margin with a rough pointed nail which had been previously dipped into the streptococcus solution.

March 31.—Brown rabbit shows marked infection with chemosis, iritis, (no exudate); 1 in 1,000 formalin solution (10 minims) were injected into the capsule. The yellow rabbit shows very slight reaction with a little redness and bulging over the site of the infection. No formalin treatment.

April 1.—Brown rabbit, panophthalmitis; chemosis; pupil filled with exudate. Yellow rabbit; practically no sign of irritation. Reinfected.

April 2.—Brown rabbit's eye destroyed. Yellow rabbit's eye seriously infected, with exudate in the pupil; chemosis. Injection of 10 minims of 1 in 1,000 formalin into capsule.

April 3.—Yellow rabbit; eye worse; great chemosis and anterior chamber filled with exudate. Eye lost.

Conclusions.—It seems fair to draw the following conclusions from the above detailed experiments:

1. Formalin, 1 in 500, may be injected into the vitreous of rabbits without producing more than momentary disturbance of the eye.

2. It is possible to cause panophthalmitis and consequent destruction of the eyes of rabbits by injecting three minims of a turbid solution of streptococci into the vitreous.

3. It is possible to produce the same result by infection in the ciliary region caused by penetrating wounds with infected pointed instruments.

4. Infections of the vitreous and ciliary region do not necessarily cause destruction of the eye. At times the infected eye recovers spontaneously, the inflammatory symptoms gradually subsiding.

5. Formalin, 1 in 1,000, when injected into the vitreous, exerts no influence on streptococcus infection of the vitreous.

6. The results of these experiments warrant the treatment of commencing infections of the eye by injections into the capsule of Tenon of 1 in 1,000 or even 1 in 500 formalin solution.

Remarks.—In view of the large quantity of infected material injected into the eyes of these rabbits it is possible that the results would have been more favorable had the injections of formalin been made more frequently.

It will be remembered, the statement has been made that in the first experiment the rabbit which had no treatment and the rabbit which had the intracapsular injections recovered completely. This is true but it is proper to state that there remained a very slight opacity apparently in the posterior part of the lens, or on its posterior capsule in each animal. This was probably due to the injury to this structure by the hypodermic needle, for it is quite impossible to perform the above detailed manipulations without struggles. This was the case with all our animals notwithstanding the free use of cocaine. It is also possible that these opacities were deposits of lymph on the posterior surface of the lens such as are frequently observed after certain types of inflammation of the uveal tract. In all other respects these eyes were normal.

"THE HEART CURE;" ITS TERMINOLOGY, PURPOSES AND ACHIEVEMENTS, INCLUDING THE ETIOLOGY OF FATTY DEGENERATION.

BY HOMER WAKEFIELD, M.D.,
OF NEW YORK.

I know of no therapeutic method within the realms of the healing art that has been more misunderstood, and, as a consequence, greater injustice has been done it than that one salvation of the victims of cardiac disease, which has so unfortunately been termed "The Heart Cure." To many superficial observers the name alone condemns it, for a *cure of organic heart lesions* is absurd on the face of it; hence by too many it is associated with the most temporary of palliative measures. Other misled practitioners have fixed ideas that only palliative and temporary sustaining measures are justifiable in the treatment of broken compensation, and actually display not only a lack of sympathy with a systematic treatment, but too often even a spirit of antagonism to the consulting physician, who proposes and superintends the "cure," is manifested.

The term *Nauheim treatment* is not very applicable to the methods, as I now apply them in New York, and even differs somewhat as applied to-day, by the different physicians in Bad Nauheim, Germany. The name "Schott Methods" applies very well to baths and exercises as I have in the past applied them at Bad Nauheim, and would to-day, if there. But, firstly, the artificial bath varies from that at Bad Nauheim, and, secondly, the bath and exercises now constitute but an integral part of the methods I now employ. Thirdly, the association of the Schott name is offensive to those who dispute Prof. Schott's claim, as one of its discoverers. So pending the general acceptance of a better name we must be content with *The Heart Cure,* as it is so universally termed in Europe.

The true aim of the modern "heart cure" is strictly speaking, neither as a palliative measure or a cure of a heart lesion. It undertakes to restore and maintain the heart's compensation, and with it the health of the dependent body. As I expressed it several years ago[12] "The recuperation of an impaired organ or group of organs is possible inversely as existing obstructions impending or arresting their normal activity may be removed." On this law the treatment is largely based.

The sufferer from heart disease, when the consultant is called in, is generally extremely low. The demands of the declining body have caused the attending physician to continually whip up the lagging heart with digitalis, strychnine, etc., until it can maintain compensation no longer and it is found in extreme fatigue dilatation and exhaustion (the cyanosis, cachexia, dyspnea and cough first greets the attention). Metabolism, especially *katabolism,* is almost nil, so depressed is the general oxidation. Anuria is pronounced, edema is quite general, jaundice is often extreme and general manifestations of autotoxication accompany the subnormal temperature, the thready pulse and perhaps a Cheyne-Stokes respiration. The family and near relatives who have gathered about the one who has perhaps for years gradually attained this low condition, have been told by the attending physician of the near approach of death and they have been prepared for the worst. Such is the situation when in ignorance of all this, the consultant is called in to do whatever is possible to prolong life and make it worth living. He has but one thought, the alleviation of suffering, at first, but as conditions improve, he commences measures of systematic and progressive treatment. As the patient continues improvement, the patient and the family begin to think about the unfavorable diagnosis, the attending physician begins to feel embarrassed, and soon he associates his troubles with the incoming of the consultant, from whom he becomes more and more alienated and estranged. These unfortunate diagnoses constitute another detraction from the popularity of the *heart cure.*

A statement by Rosenstein,[9] in 1876, of the expectant course, in *insufficiency of the mitral valve,* very well describes it, as it occurs to-day, up to the point when heart cure methods are begun, and its final termination at the time the statement was written, prior to the reformation in cardiotherapy. "The course of the disease is such that the symptoms of stagnation assume a permanent character, and all the more so in proportion to the greater number present. Though at first it is generally possible to reduce the palpitations and dyspnea by suitable diet and drugs, and temporarily even to remove all edema, yet, after a long period of alternate relatively good health and total incapacity for work, the patient becomes gradually anasarcous and exudations begin to fill up the serous cavities and impede the respiration. Bronchitis, which is always present, increases the cyanosis and whether it be accompanied or not by a pulmonic induration often developed toward the end of the disease the usual termination is edema of the lungs. In a few isolated cases the actual though distant cause of death is embolic obstruc-

tion in the cerebral vessels and its usual results, or extensive apoplexy." The death period of the old plan of treatment is commonly the one selected for calling in the heart specialist of to-day, thus terminating a period of marked decline, and a co-incident failure of the heart to further respond to cardiac tonics and stimulants, and, generally, after a goodly collection of resultant complications from vicious cycles have materialized.

My first effort in such a case is to utilize a stimulant, the effects of which have not been already "worn out," to continue the heart action, and simultaneously I begin to lessen the work of the heart and neutralize and eliminate the acid, colloid and fatty products of fatigue and suboxidation. This first effort is a temporary one, and is calculated simply as a sustaining measure, until the real treatment can be sufficiently developed to relieve the requirements for continuous stimulation. These measures are also augmented by others, reinforcing them, such as massage, warmth to the extremities, etc.

The heart cure *per se*, as I administer it, is entirely based upon a few essential physiological and pathological principles, upon which I am convinced its success entirely depends.

Present time and space at my disposal will not permit an exhaustive exposition of these basic principles, but I will briefly state that a healthy or sound heart muscle can easily, other factors being equal, maintain compensation against almost any heart lesions, embarrassing the cardiac function. My assistants, at my clinic at Bellevue Hospital, will bear me out in the statement that a recent male patient of good muscular development, who on examination at the clinic proved to have murmurs of both the aortic and mitral orifices, was daily engaged at hard labor in the subway, at which he continued after his discharge from my service. Many other laborers with more or less severe heart lesions follow their several laborious avocations, though irregular, from occasional periods of incapacity from broken compensation, from which they quickly recover upon the hospital administered *heart cure*.

Course History of Decompensation.—A heart embarrassed in its function by an orificial stenosis or a valvular deficiency is accordingly crippled, and an individual dependent upon such a heart must be accordingly considered as a person of tantamount shortened limitations, their capacities for physical exertion, endurance, bodily abuse, digestion of food, overcoming obstacles and complicating diseases, are all lessened. Intercurrent complications, as colds, fatigues, worries, anxieties, griefs, indigestions, etc., that would not seriously embarrass the vitality of an organically sound man, will quickly wreck the compensation of one embarrassed by a heart lesion. The lowered arterial pressure is easily impeded to a vital point, by the undue resistance conferred by the unequal distribution of the blood, as caused by chill, thus congesting some parts and depriving others of a sufficiency, by general circulatory stagnation of mental and nervous depression, and the deficiency of oxidation incident to muscular, mental or nervous strain. One of the first indications for relief of cardiac stress and the recuperation of the muscular function is the application of the law recapitulated at the beginning of this article, namely the equalization and entire clearing of the arterial, capillary and venous systems, especial attention being given to the pulmonary, portal and renal circulations, the obstruction of which most commonly and seriously embarrasses the freedom of the circulation.

The above quoted statement of the common course of ordinary cardiac cases, by Rosenstein, very well describes the effects of continually suffering the many pitfalls of a careless or ignorantly spent life, and its certain ultimatum. These the heart cure endeavors to prevent.

As an essential part of my plan of conservation of the patient's energy, which includes, in addition to a very careful dietary which utilizes the digestive powers to best advantage, in the ingestion and digestion of the most nutritious foods; limited to those which can be promptly digested without fermentation or perceptible putrefaction, I always restrict or entirely prohibit sexual intercourse.

PATHOLOGICAL MORPHOSIS.

All tissues are composed of cell units which are continually undergoing destruction and reconstruction (katabolism and anabolism). The circulation of the blood and oxygenation is vital to this metamorphosis (metabolism), in both its aspects. The transmission of the elements of nutrition is so well understood as to be duly recognized by all, but either from ignorance or prejudice, the subject of *katabolism* has been at all times and in all connections grossly neglected, to say the least. Most physicians will readily ejaculate that katabolism is not new to them, but when interrogated on its morphosis they prove to be not only in ignorance but directly question the truth of my allegations. Moreover the text-books are comparatively non-committal upon the details of this subject, and only by much research, can it, even by the collection of widely scattered titbits be verified.

I have by years of study and observation worked out the fact that all tissues which are deprived of a sufficiency of oxygen for that continuous combustion which imperceptibly but adequately consumes the effete eliminations from cells and the detritus of physiological cell disintegration, undergo a changed course from that observed during normal oxidation katabolism, which is characterized by radical changes in both their chemistry and their morphosis. Either by virtue of some form of suboxygenation *per se*, or suboxidation, as due to a deficiency of the necessary supporters of oxidation, namely alkaline environment and active oxidases, the results are the same. The tissues manifest a sluggishness and a reversion toward that rudimentary type of tissue, which is mostly observed in those fundamental forms of protoplasmic life (in the group intervening the monera or amebæ and the medusæ) and which

are more exposed to environmental irritations and other vicissitudes than are the higher forms of life. This tissue change differs from the normal, firstly by an increase in the size and number of cells, as a result of the stasis of katabolic oxidation, and in the presence of a continuous anabolism. The collagen of the cells is first set free during the general protoplasmic gelatinization (which characterizes its structural dissolution), part of which exudes, the balance, together with water, either absorbed from the blood or lymph, or formed during the pathological metamorphosis by hydration, combines with the protoplasm forming the characteristic gelatiniform tissue; the ultimate change of which, according to its environment and conditions of situation, being a fatty or putrefactive one, or a combination of the two. The former being the dryer one and apparently due to a synthesis of carbon and hydrogen, as set free in the incomplete formation of carbondioxide and of water. The latter being one perhaps expressing a greater excess of hydrogen and hence of water formation. However, it should be admitted here that this is mere conjecture unsupported by experiments. The sources of the water are hardly possible to determine in the living subject. Many aromatic and other toxins are, however, formed by this metamorphosis, which are not produced by normal katabolism. It is also of interest in this connection that fatty degenerations are invariably the consequence of suboxidation, whether in living tissue, dead and decayed flesh, or in the ripening of cheese. Obesity in mankind is caused by diminished arterial caliber, carbonic oxide and dioxide poisoning, tissue deprivation, owing to the counter oxidation of higher combustibles, namely ingested alcohol, arsenic, phosphorus (in toxic doses), lead, mercury, etc., which are burned in the liver, thus depriving the liver cells and thereby causing their fatty degeneration, slow asphyxiation, oxidase incapacity of impotent and castrated men and animals, and during undevelopment, maldevelopment, and temporary and permanent exhaustions and obsolescence of the sexual glands, of vices and excesses, and in menstruation, pregnancy, the puerperal period, lactation and after the climacteric, fatty and other suboxidative tissue changes are frequent. In stall fattened animals and Strasbourg geese, owing to their being deprived of a sufficiency of both air, light and exercise, fatty degeneration, general and hepatic, are the rule, especially in the liver in geese. In hibernating animals much fat is accumulated during the winter's sleep, when oxidation is almost nil, and mostly in and about the voluntary muscles where oxidation is the lowest.

The hypercombustion of the general oxygen supply of the body, as observed in hyperexias is responsible for depriving the tissues of sufficient oxygen and thus causes the fatty degeneration so frequently found in cases of prolonged high fever.

In the deficient oxidations of senile degenerations, fatty changes are observed, as well as the general fibrosis, also from subkatabolism. Tissues in an *acid* environment suffer a fatty change as distinguished from an *oxidation*, which is favored by *alkaline* media. The blood is always more fatty in the veins than in the arteries, and it might be added that putrefaction is never observed in *oxidized* (arterial) blood, but solely in the venous blood, when at all.

Atheroma of vascular walls occurs only where the oxygen supply to them is diminished either by deficiency of blood or its own oxygen contents. The least oxidated layers are those most affected.

Putrefying and decaying sausages commonly undergo the fatty change, beginning in the center of the sausage farthest removed from access of air and oxygen. In adipocere formation from decaying flesh, fat is formed at the expense of albumin, as observed after bodies have been exhumed from the grave. In certain cheeses is observed fatty formation at the expense of the casein, due to the prolongation of the ripening process. All putrid cheeses possess an increased fat content as a product of the putrefactive change.

It is of interest to mention the analogy observed in the putrefaction of wood. Woody fiber when saturated with water and kept from the air, undergoes a softening, loss of texture and disintegration, though generally terminated short of the fatty change. Analysis by Liebig[7] showed that decayed wood always evinced more carbon than did sound wood, and the oxygen and hydrogen present exist in the same proportion as they do in water. Excess of either water or oxygen will arrest the process. Liebig determined that the hydrogen undergoes *combustion* in the above process, as in distinction to the oxidation process, in which *carbon* suffers oxygen combination. It appears from the above that bacteria enhancing putrefaction, probably exhaust oxygen from their culture media, while conversely fermentation organisms appear to favor *carbon oxidation*, which is not *per se* attended by fatty changes, though its acid products must be recognized as favoring an aftercoming process of acid produced suboxidation.

In the fatty degeneration of flesh the source of the carbon of the fat has long been a subject of conjecture.

Deficiency and absence of oxidases and oxygen supporters, as sodium and other alkalies, also have been observed to favor both the physiological and pathological fat formation. Voit and Bauer[10] have experimentally demonstrated that in fatty degeneration, as produced individually by phosphorus or carbonic oxide, both the intake of oxygen and the output of carbon dioxide, are diminished below normal, and that the process is accompanied by an increased output of urea, thus showing that the process of fatty change includes a coincident destruction of the nitrogenous elements, which are eliminated as urea, while the carbon elements seem to remain and suffer the fatty change. Here again we observe a perversion from the normal process, for with adequate oxidation and in beginning degenerations, even from suboxidations, the cells first part with their car-

bon elements, as is observed with the physiological tissue discharge of glycogen as dextrose. An extreme opposite to these processes is found in diabetes mellitus in which the entire proteid molecule is broken down, and in the deficiency or absence of oxidation, is eliminated as a great excess of both urea and glucose in the urine. Arteaga and Lusk[1] assert that 60 per cent. of the proteid molecule is resolvable into dextrose, hence the source of carbon in fatty degeneration is apparent. I have in the past, in common with many other observers, been misled by the enormous output of urea, into the belief that we have in diabetes a greatly increased *metabolism,* but elimination and metabolism are two different things, and my own researches certainly indicate in no uncertain terms that metabolism is not a unit of observation. Only by recognition and observation of normal and morbid *anabolism* and *katabolism,* as separate entities, are we enabled to intelligently and correctly recognize and draw accurate deductions from estimations of the intakes and outputs of metabolic processes. Thus both active and stagnant katabolism may be attended by an increase in the output of urea; in the first place by the increased oxidation by the carbon elements, as in active exercise, the normal activity of katabolism being parallel with the slightly increased urea output, and in the second place, where the active degeneration of the pronounced katabolic stasis of extreme suboxidation as in advanced diabetes mellitus, in which the cells are broken down so rapidly that both nitrogenous and carbon elements are eliminated together. Then the fatty degeneration comes in as an intermediate stage, in which the degeneration is less rapid, the katabolic stasis is more marked, the output of urea elimination is intermediate between the normal and the diabetic extreme, and the fatty metamorphosis of the 60 per cent. of carbon constituent of the protoplasm is in evidence.

An initial expression of protoplasmic suboxidation is a dissolution, separation and exudation of the collagenous elements of the cells, generally associated with the presence of an unusual amount of water; first observed in mucous and serous membranes and other epithelial tissues, or more rapid processes may be manifested by the gelatiniform or colloid degeneration of the least oxidated cells, during the process of which the vascular system becomes involved in the general accumulation in the system of colloid tissue detritus. In ratio to the relative efficiency of the several blood glands, including the liver, where the oxidation of the blood contents is the highest, the eliminations vary in the proportion of urea and ammonia, and the blood frees itself from the obstructing colloid detritus.

The blood, like the tissues, is seriously disorganized and degenerated, in proportion as it is suboxygenated and suboxidated. In addition to oligocythemia, leucocytoses and general cellular degenerations that are observed, it is important that suboxidation causes the blood to lose its normal powers of coagulation and singularly the coincident degeneration favors the formation of thrombosis and embolism. Reoxygenation promptly restores the coagulability and gradually overcomes the disposition to thrombi formation.

The closest analogy, I know of, to the degeneration of the cardiac muscle as a result of fatigue (sarcolactic acid), caused suboxidation, is that of the hound-chased hare, which after being entirely exhausted by fatigue (*run down*), its flesh immediately enters a fatty putrefaction without even first passing through the stage of *rigor mortis.* Obstruction of the coronary arteries is a potent cause of fatty heart, but suboxidation from muscular overwork and fatigue is a much more prolific cause.

In pronounced anemia, in cases of poverty of hemoglobin and of the entire blood volume, as after bleeding, we have the closest analogy to the suboxygenation of cardiac deficiencies, and their prime physical expressions are identical, namely colloidation and fatty degeneration. These processes vary in proportion to each other, in individual cases, and in different diseases, as governed by the general laws above mentioned.

All pernicious blood diseases which are attended with oligocythemia, and their oxidation degradations, as chlorosis, leucemia, pseudoleucemia, anemias, and especially progressive pernicious anemia, produce gelatiniform and fatty degenerations very similar to those observed in the suboxygenations of cardiac deficiencies. The general relaxed and flaccid condition of the tissues, the limp and languid state of the muscles, the succulence of the cells, the atony of the stomach and the general organoptosis tell of the general tissue gelatinification. The marasmi, edemas and hemorrhagicas indicate, in addition to the above condition, the implication of the vascular walls, the broken integrity of the blood and the dissolution of its constituents. The oligocythemia, the leucocytosis, the increase of urea and the diminished carbonic dioxide outputs, together with the subnormal temperatures show both the cause and effect of the suboxidation. Dilatations of the cardiac muscles occasionally occur unpreceded by hypertrophy, thus showing a skip over the period of nutritive gelatinification to that of textural laxity as manifested in the dilatation. The common occurrence of ulceration, fatty degenerations and the disposition to the formation of malignant growths and to pulmonary tuberculosis, as an ultimate termination, are to say the least, significant.

The irritable weakness of patients of these subkatabolisms, of both oligocythemia and cardiac deficiencies, and of the oxidase incompetencies of sexual evolutions and depressions, simulates common ailments characterized as of nervous origin; also, it may be added that extreme suboxygenations from any of the above-mentioned causes are responsible for muscular tension, spasms or epileptiform convulsions.

The idiopathic anxieties of heart disease are manifestations of this same irritability which assumes the form of spasmodic contractions or

convulsions in extreme conditions, and these conditions being less compatible with life than the relaxed ones, narcotics are administered as a choice of evils, the general basic condition being afterward restored by oxidation.

Colloid detritus does not *all* undergo fatty degeneration. Some of it suffers putrefaction, as also all gradations between putrefaction and the fatty change. Of course, more or less of it finds a partial or complete oxidation in some favorable situation.

Victims of cardiac debilities, in addition to the pronounced degenerations above described, also coincidently develop the milder grades of gelatinization of the whole body, which confers a kind of diathesis, by virtue of which marked degenerations are more rapidly and easily developed in susceptible situations. This condition finds frequent expression in the pulmonary tissues, which become gelatinized or even indurated; serous and mucous exudations cause vicious cycles by further embarrassing respiration, and hence oxygenation. The imperfect integrity of the lung tissues dispose them to permit hemorrhages and cause hemorrhagic infarctions, in events of pulmonary vascular engorgements that otherwise would be insufficient. The entire vascular system, owing to gelatiniform changes, suffers serum exudations, causing anasarca, when the blood tension is anything but high; though it must be admitted that changes in the blood itself are partly responsible for it. Vascular incompetencies in the brain also are thus manifested by apoplexy and by fatty changes.

There is an impression by many that the greater tenderness of the meat of stall-fattened animals is due to the cooking of the fat with the lean. This is not the case, however; the same suboxidation which is responsible for the fattening of the animal is also the cause of the softness and succulence of the lean tissues. The well-known effect on castrated male animals and the greater tenderness of the meat of the ox and the cow than that of the bull, and the greater ease with which they are fattened, accords with the observed relation borne by sexual virility to oxidation in man. The softening of meat due to prolonged keeping is equivalent to that due to suboxidation, both being due to degenerative processes.

It may be added that all tissues suffer a vicious cycle, for the accumulation of the maloxidized products of muscular metabolism add to the obstacles to further oxidation.

The heart muscle itself is a sufferer from subkatabolic degeneration. As a result of its first overwork, the formed *sarcolactic acid* lowers its oxidation, a corresponding slump occurs in the ability to oxidate the muscle, and the later formed acid. As a result of the tissue suboxidation we have first a nutritive hypertrophy (by virtue of which nutrition "phagocytosis" is augmented). Then, with the process of the gelatinization the hypertrophy is maintained or enhanced simply by the katabolic stasis in which normal anabolism maintains the balance, the katabolic oxidation and elimination being almost nil. The next stage, we may picture the fatigue extension of the muscular fiber, in which we may assume the muscular hyperplasia to have suffered a change to a longitudinal prolongation, thus the heart passes from a hypertrophy to a dilation, and with its extension of equilibrium length we observe a curtailment of its functional capacity.

The Author's Method of Treatment.—All these conditions must be remedied or the *Heart Cure* must itself prove a failure and the patient must pay the death penalty.

By the aid of my temporary prolongation of the heart's stimulation I endeavor simultaneously to restore the systemic oxidation, to lighten the load as much as possible of the heart's laborious task, and to rid the system of the autotoxication which incidental putrefactions have caused. The former is accomplished by the free inhalation of an abundance of *nascent* and purified oxygen gas, made fresh several times daily, not far from the bedside. It is administered through a tube from a convenient tank, or the whole atmosphere of a small room is impregnated to a point relieving the patient entirely of undue respiratory effort. If the patient is unable to acquire perfect oxidation from the oxygen alone I make up my mind that as the oxygen is fresh and pure, that the trouble is with the patient's powers of oxygenation or oxidation, and in view of the fact that deficiency of hemoglobin, alkalies and oxidases are almost the sole causes of such failures, I proceed to increase these factors, by administering iron internally, and enemas of 50 to 100 per cent. saturated solution of sodium bicarb., inflating the colon, with the temperature at blood heat. If the condition is very low I often add to this a quantity of hydrogen peroxide, which I vary acording to my judgment; also, in suitable cases, I add sodium chloride C. P., which I also vary according to the demands for additional stimulation. The other method employed is the administration of an active oxidase. I have been giving internally a glycerophosphate, or when the patient's stomach is irritated by the glycerin, and often otherwise, for a change, I give a phosphorated oil, preferably a cod-liver oil (but not with hypophosphites). The recently introduced sterilized tubes of glycerophosphates for hypodermic injection which have become so popular in Europe, bid fair to supplant the *internal* preparations for these purposes.

For the second indication, namely the clearing of the vascular system, I clear the portal system by oft repeated, very small doses of calomel and a saline cathartic. By warmth to the extremities I draw the blood as far as possible from the venous splanchnics and cause a determination of blood to the periphery, by cold water taken internally, between periods of eating and digestion. But the restoration of *oxidation* is by far the best remedy for the clearing of the circulation, the relief of resistance to arterial flow and the consequent relief to the heart.

For the third indication, the reoxygenation of the tissues is unparalleled, but the relief of serious anurias is so imperative to the acomplishment of that end that I must grant what its importance deserves, and here I must relate that in my hands, teaspoonful doses of hydrogen peroxide every three hours have restored the twenty-four hour urine to above 50 ounces in cases where one-twenty-fifth grain doses of nitroglycerin had singularly failed.*

It is of interest here to relate that I have repeatedly, promptly arrested cardiac hemorrhages with immediate inhalations of nascent oxygen gas, and by oxygen inhalations combined with soda *colon* injections I have promptly controlled and entirely reduced marked thoracic and abdominal dropsies, in one case within four days, that had previously been tapped twice weekly.

After the patient's improvement, to a point of sitting up a few hours daily, I hasten its continuance by light frictional brushings and massage, and I begin the bath treatment by immersing the feet in a carbonic acid or a capsicum bath, to be followed by the full brine and carbonic acid baths and the resistance exercises. Thus we accomplish the determination of the blood from the splanchnic to the superficial circulation, and from the intestinal vessels to the capillaries of the muscular system. The increased respiration and the reaction from the loss of heat, as do the exercises, greatly accelerate the general oxidation processes of katabolism, and the toning effect incident to it all is the result of the restoration of the muscular tissues which have generally suffered a subkatabolic and hyperplastic extension of the equilibrium length. I have no hesitancy in stating that the real secret of the bath cure lies almost entirely in its physiological effect, as a *cold bath* and that the carbonic acid and alkalies simply counteract the cold by stimulation, and make it possible for a person with cardiac debility to react against and after such a bath, from a temperature which they otherwise could not tolerate. Though carbonic acid is very exhilarating, other stimulants, as capsicum, mustard, ginger, pine needles, etc., are just as good and accomplish the same results. They are superior, in cases where patients do not well tolerate the inhalation of carbonic acid gas given off from the bath, and from which it is difficult to effectually shield the patient.

It is observed that the two principal degenerations of heart disease, namely gelatiniform and fatty metamorphosis, are entirely due to and dependent upon the suboxidation which results from cardiac and blood deficiencies and their vicious cycles, and are preventable, arrestable and restorable in the great majority of cases.

Where colloid degeneration is active, uric acid, as well as other suboxidation tissue products will be excessive, and at such times the portal oxidation of nitrogenous foods may be subnormal, and uric acid may appear from the nuclein elements of meats ingested. In event of such experiences, patients should be warned against Haig's methods of discontinuing red meats, veal, etc., which are of great nutritive value. Bear in mind that if the oxidative processes are ample for tissue katabolism they should be sufficient for proteid food. If both carbohydrates and proteids cannot be eaten, drop the former rather than the latter. Remember they are sometimes incompatible, but often a certain amount of a diffusible alcohol, whisky or brandy, will enhance proteid combustion, while a greater amount, or the same in carbohydrate combination will lessen it.

I have purposely omitted the consideration of the administration of iron, in cases of reduction of the hemoglobin index, for the reason that I assume that its place in medicine is already established. However, I must protest against the indiscriminate use of iron preparations in those other cases of debility, which are assumed without analysis of the blood, to be indications for iron.

Digitalis, while a most valuable drub for cardiac stimulation, is one of the most abused drugs in the pharmacopeia. Its further consideration I will not attempt here.

There are two drugs which, by comparatively recent demonstration, have proven to be very potent in these subkatabolisms, for drawing together and restoring tone in the relaxed tissues, which are administered by hypodermic injection, namely ergot and adrenalin. I have found them both of untold benefit in well-adapted cases, but the last named is a dangerous drug for careless prescribers, and when given by an attendant unskilled in its use, for *in nature* the adjustment of its supply by the adrenal glands is normally very accurate and fine, whereas pernicious results are often obtained by patients themselves or nurses administering it in the physician's absence, by unduly prolonging it beyond attaining the physiological effects, which they fail to recognize.

The proper adaptation of strophanthus, cactus, sparteine, caffeine, strychnine, nitroglycerin, amyl nitrite, quinine, potassium, iodide, etc., I make use of, as they are indicated, and following the rules commonly in vogue as recorded in the textbooks.

For reasons above recorded, arsenic, phosphorus (in excessive doses), lead and other metallic oxides (even mercury, in large doses) dispose to lower oxidation, and are distinctly contraindicated.

Continuous "doping" with liquors is to be discouraged. When uric acid, colloids and other vascular obstructions accumulate in excess, the most highly oxidizable and diffusible forms as whisky or brandy, are indicated, only for a few doses, best given in milk, to clear the portal circulation. However, for this purpose occasionally lemon juice or a citric acid beverage is best. In proportion as the alcohol is combined with carbohydrates, as in beer, porter, ales, stout and sweet wines, or, as wines that are very acid, the tendency to uric acid and colloidal increase is caused.

*I prefer the peroxide of hydrogen possessing the lowest acidity to the volume strength. Acid preparations will increase the anuria.

When not continually given, it is a very valuable stimulant for emergencies.

Both ice water and sulphuric ether, the latter in 10-drop doses, I have found valuable when administered just preceding food, as a help against the expulsion of the food (vomiting) in suitable cases. Rest in bed I compel until the compensation is sufficiently restored to insure freedom from ankle edema, while in the erect position, at least two hours daily.

I often institute full baths before the patient is able to walk to and from the bath, even from one room to another. The exercises I reserve until the compensation is fully restored, and until they can be given without fatigue to the patient. The least manifestation of fatigue or strain is an indication to desist. High blood pressure I reduce by freeing the circulation, as above narrated. Hemorrhages I always treat by the inhalation of oxygen, and internal administration of adrenalin and oil erigeron. The latter acting, I believe, as an additional oxygen carrier.

Intestinal putrefactions, autotoxemia, uremia, bradycardia and Cheyne-Stokes respiration are all indications for local or general increase of oxidation, and are due to toximias of suboxidation.

The rehabilitation of compensatory hypertrophy, I interpret to be a manifestation of enhanced oxidation of the heart, both owing to its reduction of volume, its decrease of equilibrium, length of the muscle fibers, and its consequent increased functional power and capacity.

Many intercurrent diseases and conditions exert marked influences upon the conditions present, which the well-informed physician will recognize and properly treat.

In cases when glycerophosphates are administered by the stomach, physicians must carefully discriminate against all the proprietary preparations containing an abundance of *alcohol* and *sugars*, in combination, which, while very palatable and elegant from the pharmaceutical standpoint, are practically worthless from the medical point of view, owing to the fact that the alcohol and sugar, as burnt in the liver, produce suboxidation in the same way, and quite as much as sweet wines, which will nearly or quite offset the good effects of the glycophosphates, and may cause fatty liver or gout in the bargain.

Users of oxygen which is more than twenty-four hours old, especially that compressed in tanks, will fail to obtain the results I have described. Absolutely pure and nascent oxygen, in my hands, has given the best results. The compounds of oxygen with nitrous oxide gas, *when fresh*, in the proportion of five parts of oxygen to one part of nitrous oxide, are occasionally a benefit in cases of cardiac excitabilities and anxieties.

In those cases where the bile pigments are deficient or absent in the feces and also where the ingested fats are immediately eliminated in the feces, instead of being conducted into the portal system; in both instances causing a superpale yellowness of the stools, I have found the administration of ox-gall and pancreatin with an excess of sodium bicarb., on an empty stomach of great value. In the first instance, the ox-gall supplies the general demands of intestinal digestion, and in the second case, it neutralizes the deficiency of bile in the assimilation of fats and makes possible their assimilation during periods of decline, otherwise impossible. I have found cod-liver oil of greater value than other fats in these cases, owing to its content of biliary elements.

After the patient has been restored to an apparent robust health, before the physician takes his leave, the patient should be given *a lecture*, a warning, as to his shortened limitations, how to maintain his compensation and oxidation, how to live within his limitations, at a happy neutrality between the extremes of overdoing on one hand, and a too sedentary life on the other. He must be taught how to eat, what to eat, what to wear, to avoid a chill, worry, mental, nervous and physical strain and fatigue.

Physicians should never neglect to inquire for specific histories in all heart cases, for, in my experience, they are not uncommon and they are the most difficult and unsatisfactory to treat, and they are the first to backslide and prove unresponsive to the best treatment. Even these cases, however, are well worth treating, and often admit of brilliant successes.

The acute heart failures, which sometimes occur without known cause, should receive a passing mention, for some of their manifestations are not sufficiently described in the text-books, and they are very significant to the expert. The so-called idiopathic anxieties of heart patients must be distinguished from the worries and anxieties of other troubles. A sudden development of nervous unrest, an intense picture of anxiety upon the face, with prominent veins, when associated with dyspnea, cough, distress, palpitation or oppression should receive prompt attention with potent restoratives. In such cases the writer has often responded with ammonia aromat., strychnia, digitalin and morphine simultaneously, the latter three hypodermically, in order to meet the requirement. Idiopathic abdominal pain, another symptom of acute heart failure must be met as above. In these cases, however, gelatinization of the vascular walls has, together with venous engorgement ultimately overdistended the splanchnic veins, and the pain is the result. The hypodermic administration of ergot or adrenalin, often accomplishes the contraction, and expulsion of the surplus contents of these veins. And in all of these oxygen inhalations, colon irrigations with normal salt solutions and sodium bicarb., hot fomentations to the extremities all help to tide over these cases until other measures can be adopted to meet the more "chronic" indications.

Nothing, other than narcotics, allays pain like bland alkalies, when brought in contact with the seat of the pain, even pain of the most severe burns is allayed and best treated by alkalies, dry, or in oil mixtures.

There are many persons both inside and outside of the medical profession who discourage the *heart cure*. They taboo the idea of treating and prolonging life, in these cases, which so invariably have heart lesions which cannot *per se* be cured. This, however, I believe to be a great mistake, as, for the patients personally considered, I never met one who did not desire his life prolonged, and a restoration, of even ever so limited possibilities for future usefulness. Many men, at a time of life when they have acquired heart disease of serious import are so situated that the family sustenance does not depend upon hard labor, and their advice even, coupled with a long ago obtained knowledge of a business or enterprise, is of great value to his interests, or that of his successors. When independently wealthy, a man's or woman's prolonged life, if comfortable, happy and free from pain, is a great source of happiness to their family and friends. Often mercantile or other business houses will continue to pay large salaries to valuable employes, even if incapacitated for any but light mental work and valued opinions. I have friends in the profession, who, with shortened limitations and artificially sustained compensations, have practised the lighter specialties in medicine for many years, to their own satisfaction, profit and happiness.

Very often a physical breakdown will come to men who are entirely unprepared for it, and their death at such a time would prove a great calamity to their interests, and to their families. I have had the satisfaction often of restoring and maintaining men under such circumstances, and even tided them over until sons could be taken from school and trained, under the advice of the patient, to successfully conduct large interests. I have a gentleman now under my occasional care, who as custodian of one of the great New York municipal institutions, is on his feet daily, Sundays included, from eight to twelve hours, yet he has a severe heart lesion, and has been rescued from imminent death two or three times since I first assumed his care three years ago. Many persons, rescued by the *heart cure*, live many years, and very useful lives, even to die finally of some disease other than of the heart. Some attain quite a ripe old age, with very good compensation and oxidation, while others, for one reason or another, do not live out one additional year. Altogether, however, it favorably compares with other special lines of practice.

My object in contributing this monograph, is not to set forth any personal accomplishments, or brilliant achievements, but rather to give to the profession, as completely as my space will permit, a plan of treatment, based upon what I believe to be a sound etiology and pathology, which has been successful in my hands and which has convinced me will lower the present cardiac mortality over 50 per cent., when in general utilization by the profession. For further exposition of the physiological effects, I refer the reader to my former article.[12]*

*The bibliography of this monograph on the heart is so full as not to require repetition here.

Notwithstanding my desire to see my methods universally adopted and improved upon by other men, my knowledge of the pitiable ignorance of so many professional men on heart physiology, pathology and therapy, causes me to include a word of caution to such men, not to undertake the treatment of cardiac cases without a thorough foundation of information and experience in this line, not excepting a good knowledge of the modern methods of physical examination and diagnosis.

I have purposely limited my article to a treatment basis, that I feel has elsewhere been neglected or undeveloped, and I have made no effort to compass the *full scope* of the therapentics, even as I practice it; for that, the reader must be referred to the text-books and special works on the heart, and, if possible obtain hospital experience. Bath-house attendants and nurses should be forbidden by law from attempting the administration of *heart* treatment, except under medical superintendence, for it must be understood that these methods are not necessarily harmless in ignorant and inexperienced hands, and that there is nothing so easy as to injure or kill a heart patient, simply by mistakes that would be almost immaterial in the treatment of many ailments.

It is not the mechanical difficulty of giving a bath, but the knowledge and skill necessary to properly treat a person so vitally afflicted, that should cause this treatment, in all its phases, to be wrenched from unskilled and unprofessional hands.

The superiority and essential requirement of a medical man, in these cases, lies not only in his resourceful general knowledge of heart diseases and its resultant and complicating conditions, but also in his skill in the delicate adjustments, which are so necessary to success. Even trained masseurs and other attendants upon caridac patients often require the strictest superintendence by the attending phyician, to insure against awkward, indelicate or careless attentions, thus overexerting the patient, underexerting themselves, or rough handling and careless assistances and administrations.

I have occasionally found it difficult to secure capable persons for the administration of the baths and exercises, even from the ranks of trained masseurs. Even towel rubbings are applied so vigorously and regardless of the patient's tolerance of it as to bring on extreme fatigue, prostration and in consequence acute heart failure, which often requires days or weeks to overcome.

151 West Seventy-sixth Street.

THE RELATION OF MILD TYPES OF DIPHTHERIA TO THE PUBLIC HEALTH.

BY THOMAS W. SALMON, M.D.,
OF WILLARD, N. Y.;
BACTERIOLOGIST NEW YORK STATE HOSPITALS.

No one who has occasion to examine much that has been written about diphtheria during the last fifty years can fail to be impressed by the noticeable decrease in the volume of the literature of the subject during the half dozen years just passed. It is probably not true that, even with the passing of its terrors, diphtheria has lost much of its interest for physicians, for, although it may no longer be called "the most dreaded disease of childhood," its victims are still numbered by thousands. It is controversy, in medicine, as elsewhere, which drives people to their pens, and recent researches have taken so much that relates to the causation and diagnosis of diphtheria from the arena of the medical journals and placed it among the well-demonstrated facts of medical knowledge that the unending discussions of the last generation find no place in the literature of today. The great importance of the bacteriology of diphtheria has lately overshadowed its clinical aspects, and this, perhaps, by limiting the number of contributors, has lessened the output of medical articles.

It is possible that the future will not provide material for such accounts of great epidemics of diphtheria as help to fill the early transactions of state medical societies and the health reports of England. A study of some of these in the light of our present conceptions of the transmission of disease is wonderfully interesting. Minute descriptions of house-epidemics and school-epidemics, which were intended to prove conclusively the malign influences of ground air and "diphtheria-bearing clays" are invaluable mines from which to obtain confirmation of modern ideas as to the spread of this disease. And yet one is continually struck by the shrewdness of the opinions advanced by some of the earlier writers, and by the closeness with which deductions reached purely by the exercise of logic correspond with the results of the laboratory work of the last fifteen years.

It is hardly possible to state where the earliest record can be found of the fact that *during epidemics of diphtheria, there is usually an increase in the prevalence of simple sore throats,* but the literature to the present time is filled with its repetition. A report of an epidemic in Delaware County, which was presented at a meeting of the New York State Medical Society in 1861 contains the following:[1] "Every reddened throat was not diphtheria, while a very few throats in a circle around the focus, whose diameter was a mile or more, whether young or old, *failed to exhibit more or less traces of the prevailing epidemic influence.*"

Dr. Franklin Parsons, in a report on an outbreak which occurred in 1887 in the parishes of St. Stephen's and Roche, England, says:[2] "As regards the means by which the disease was spread, I am of opinion that, in most instances, its occurrence may be accounted for by infection from a previous case, more especially if we may allow that the known cases of diphtheria were accompanied by a number of mild, unrecognized ones. I learned from more than one source that sore throats were very prevalent in Roche last autumn. Thus the schoolmaster at the Roche Board School states that at the time diphtheria was prevalent, and to a less degree before and afterward, many of the school children had sore throats and used to come to school with their necks tied up in flannel. Experience gained elsewhere has shown that outbreaks of diphtheria are frequently accompanied by a similar prevalence of sore throats not distinctly diphtheritic in character, and has shown it to be probable that, though such cases may not, from a clinical point of view, come within the definition of diphtheria they are essentially of the same nature, and that a susceptible person coming in contact with one of them may contract the disease from it in a severe form."

Physicians and nurses are particularly likely to have such sore throats. A friend of mine tells me that more than once while he has been in close attendance upon cases of diphtheria he has had a violent pharyngitis which did not yield readily to ordinary treatment, although frequent examinations of the throat failed to reveal pseudomembrane.

It is needless to multiply such references, for most physicians who have had outbreaks of diphtheria in their practices can recall instances where mothers and nurses of sick children have been affected with this form of sore throat, and, indeed, the matter has received sufficient notice in most of the text-books.

It is with the diagnosis and management of such cases that we are especially concerned with reference to the public health. It is most essential that their existence should receive official recognition and that they should be assigned a definite place among the varieties of diphtheria.

As Dr. H. W. Hill has pointed out,[3] a number of different conditions may follow the infection of an individual with the bacillus of diphtheria. The disease which we all recognize as diphtheria, with the presence of pseudomembrane and the evidences of systemic poisoning, results from the infection of a susceptible person with virulent diphtheria bacilli. When insusceptible persons become infected with virulent diphtheria bacilli no lesions result, but, as is well known, the bacilli may be transmitted to susceptible persons

and cause the disease. That such infected well persons are a common and potent cause of the spread of diphtheria has been abundantly shown by recent investigations.[4]

Susceptible persons may become infected with diphtheria bacilli wholly lacking in virulence. No lesions follow this occurrence, and the spread of the disease is not aided by such persons, for it has been shown that non-virulent bacilli do not regain virulence readily, if at all.

In this paper it is with two other combinations of the diphtheria bacillus and the individual that we have to deal. Relatively insusceptible persons may become infected with virulent diphtheria bacilli and susceptible persons may become infected with feebly virulent bacilli. In both of these instances the resulting condition is the simple sore throat so prevalent during epidemics of diphtheria. Perhaps the greater number of these cases arise from the insusceptibility of the individual, and this insusceptibility in the vast majority of instances, is due to the immunity conferred by age.

The nomenclature of the various conditions just referred to is a matter of some importance. Several names have been suggested for the simple pharyngitis due to infection with diphtheria bacilli. "Catarrhal diphtheria," "bacteriological diphtheria" and "diphtheritic sore throat" are some of them. It is very important that the name selected should not permit the condition to be confused with that very different one, pseudodiphtheria, the essential feature of which is the presence of a membrane resembling that of diphtheria but due to other organisms than the Klebs-Loeffler bacillus. "Diphtheroid" would be an appropriate name for the condition, for it is *like* diphtheria in the most important feature—the presence of diphtheria bacilli—and the name might suggest to the public the somewhat analogous "variola" and "varioloid," but unfortunately the name diphtheroid has already become associated with pseudodiphtheria. Perhaps catarrhal diphtheria is as good a name as any of those which have been already suggested.

The diagnosis of catarrhal diphtheria (to continue to use that name for the present) *depends entirely upon bacteriological examinations.* However suspicious the circumstances surrounding the case may be, or however direct the history of exposure, it is obvious that a diagnosis cannot be made with certainty without taking cultures. In cities where bacteriological laboratories are maintained by the Boards of Health this is no particular disadvantage, but in places where such facilities are lacking the diagnosis of catarrhal diphtheria must be an exceedingly rare one. When an outbreak of diphtheria is in progress, in even a remote village, with an unusual prevalence of sore throats and especially when these seem to be responsible for the continuance or the epidemic, it may become necessary for the local health authorities to have cultures taken, and it is interesting to know that in New York State there is no place more than 100 miles from a laboratory where work of this sort could be done. Inoculated culture tubes have been received at the laboratory of the Willard State Hospital after being three days *en route* in both winter and summer and satisfactory growths of diphtheria bacilli obtained from them.

As to the frequency with which cases of catarrhal diphtheria occur there are no adequate means for determining. It has been suggested that the unrecognized cases in an epidemic exceed in number those which are detected. Diphtheria has prevailed at the Willard State Hospital for four years. During that time 158 cases of pharyngeal diphtheria have occurred, four cases involving the larynx, six cases of nasal diphtheria and one in which the vagina, the rectum and the fauces were all involved. From the commencement of the epidemic, every case of sore throat of whatever nature which has occurred among the 2,700 patients and employes residing in the institution has been scrutinized very carefully and a culture taken. There have been found nineteen cases in which redness and swelling of the throat with constitutional disturbance have been accompanied by the presence of diphtheria bacilli. These cases presented absolutely nothing by which the diagnosis could have been made without the aid of cultures. The persistence of the bacilli and the consequent duration of quarantine did not differ from that in cases of "true" diphtheria. As nearly all the people exposed were adults, it might have been expected that the number of catarrhal cases would have exceeded 7 per cent. of all. A few cases among the inmates undoubtedly have escaped notice.

The management of these cases of catarrhal diphtheria is the *crux* of the whole matter. It will be conceded by every one that the first essential is that physicians admit that diphtheria bacilli may be the cause of an inflammation of the throat in which no pseudomembrane is formed and that such cases are quite as capable of causing others as cases of "true" fibrinous diphtheria. It is useless to call them "diphtheria" without a qualifying adjective for the laity from whom, we must not forget, all our quarantine laws have their origin, cannot easily be persuaded that the disease which strangles the little child and the one that causes a transient swelling of the mother's pharynx and tonsils differ only in degree, but if the term "catarrhal diphtheria" (or a better one) be given as definite a clinical application as "varioloid" there is hope that it would speedily find a place in our sanitary laws. Like persons with the ambulatory form of other diseases, those suffering from mild forms of diphtheria are a source of much more danger than those "safe" in bed.

With the facts just stated in mind there can be little difference of opinion as to the measures which will best serve the public health in dealing with cases of catarrhal diphtheria. The condition should be included, under its own name, in the list of notifiable diseases. The same sanitary regulations which relate to the management of diphtheria should be extended to it and, as its recognition depends wholly upon bacteriological ex-

aminations, it is evidently a public duty to provide facilities for this work. That the spread of diphtheria and the continuance of many prolonged epidemics depend, in no small measure, upon these cases of mild diphtheria in adults is a fact which cannot be ignored.

CHRONIC VILLOUS ARTHRITIS, WITH SPECIAL REFERENCE TO ITS ETIOLOGY AND PATHOLOGY.

BY CHARLES F. PAINTER, M.D.,

AND

WILLIAM G. ERVING, M.D.,

OF BOSTON.

(Continued from Page 920.)

Case No. 23.—October 31, 1902. R., male, twenty-six years of age; a teacher by occupation. Diagnosis, loose cartilage (semilunar). The exciting cause of his illness is trauma. The onset occurred in October, 1902, due to an injury in a football scrimmage. It was accompanied by pain, swelling, limitation, locking, and partial loss of function. No treatment for three weeks, then fixation in plaster. The right knee-joint was involved. It was slightly swollen, had the normal amount of motion in flexion, and could not be completely extended. Palpation was negative. Tenderness over int. condyle. A lateral internal incision was made and the capsule was found to be normal with a slight excess of fluid. Partially detached semilunar cartilage removed. There was one fringe which was attached to the inner ligamentum alæ. The fringe was irregular in shape, of a reddish-purple color, and a soft consistency. No hemorrhage, and irrigation and ligatures were not used. The capsule was closed with silk, with no drainage. Plaster splint applied. The stitches were taken out in one week, and manipulation was tried at the same time. The treatment consisted of flannel bandages and daily manipulations. On January 6, 1903, the amount of motion was normal, there was no swelling or pain, and the functional result was perfect.

Pathology.—Specimen consists of two hypertrophied synovial fringes from behind the patellar tendon, vascular, and of a fatty consistency, 1- 1.5 cm. in diameter. Also thin narrow strip of cartilage which had become almost entirely detached and blocked to some extent the normal joint function of right knee. Microscopical. Periphery of section deeply infiltrated with round cells and very vascular. The central portion consists of adipose tissue with thin feebly staining strands of connective tissue scattered throughout, and the vessels are fewer and of large size for the most part.

For Case 24 see *Boston Medical and Surgical Journal,* March 19, 1903.

Case No. 25.—December 28, 1902. A. D., male, twenty-eight years of age. Diagnosis, trauma. The patient's family and past history are negative. His present illness dates back to an injury to the knee eighteen years ago, caused by trauma to knee due to a fall. The joint is painful in walking and is swollen. Some flexion is possible and the function is impaired. Arthrotomy was performed at the Carney three years ago. Recurrence followed two or three slight injuries. The right knee was involved and swollen, suggesting rheumatoid. Motion quite free. A considerable fringe formation could be palpated and there was no tenderness. A lateral incision over the inside of the joint was made. No fluid or fibrin was found, but several small fringes and considerable thickening and some adhesions. In the treatment no ligatures or irrigation were used. The capsule was closed with silk, was not drained, and a plaster dressing applied. The stitches were taken out in one week. In February, 1903, flexion amounted to a right angle with no swelling or pain and a good functional result.

Pathology.—Fringes from internal and external portions of knee-joint, bound down for the most part and not easily separated. They entirely blocked the joint space. They were removed in small pieces, and had a fibrous quality. On the outside of the joint was an accumulation of tissue of necrotic appearance, resembling a cyst, which contained a small amount of fluid from which no cultural growth was obtained. Microscopical. Feebly staining fibrous tissue in one portion of the section, which did not contain the cortical portion of the mass of tissue in its entirety. This tissue becomes more and more infiltrated with adipose tissue on going inward, until adipose tissue cells of larger size, and an irregular network of slender, twisting, feebly staining fibers fills the field. There are numerous vessels, their walls much hypertrophied, and their lumina often obliterated, while the nuclei of their sheaths stain brightly.

Case No. 26.—December 31, 1902. L. A. G., female, thirty-two years of age. Diagnosis, loose cartilage. Her family and past history are negative. The exciting cause of her present illness was a fall on the left knee four years ago, in 1898. The patient fell, striking her knee on the sidewalk, causing pain, and a slight swelling below the patella. Motion is limited to 50° of flexion, guarded. There is no locking, and a partial loss of function. At the time the patient was laid up for five weeks, and in 1899, and again in 1900, the knee-joint gave out. This last time the knee was operated upon and a fringe removed. In January, 1901, the soreness returned.

The patient was a soft, flabby woman. Her left knee-joint was involved, slightly swollen in appearance, with 50° of flexion, palpation negative, and tenderness over attachment of semilunar cartilage. A lateral incision was made on the inside of the knee-joint, showing no fluid or

fibrin, but a good-sized lipoma and a detached internal semilunar cartilage. The fringe was vascular, yellow, and of a soft consistency. There was no hemorrhage. No ligatures or irrigation. Silk was used to close the capsule. It was not drained and a plaster dressing was applied. On May 8 the amount of motion was more than a right angle, with practically no swelling, no pain, and the patient used the leg freely.

Pathology.—Specimen consists of dark, firm, cartilaginous appearing mass, 2 cm. in length, and a mass of soft tissue, 2x2 cm., from interior of knee-joint. The latter is reddish in color, slightly lobulated, fatty consistency, resembling a degenerated fringe. Microscopical. Specimen consists of a mass of pure adipose tissue, save for a few thin striæ of connective tissue and two irregular solid masses of this tissue with few feebly staining nuclei and the appearance of advanced necrosis of granular and hyaline type. On this latter tissue are a few cells which apparently represent the remains of atrophied vessels. Throughout the section no patent vessels.

For Case 27 see *Boston Medical and Surgical Journal*, March 19, 1903.

Case No. 28.—February 10, 1903. M. C., female, thirty-two years of age. Diagnosis, trauma. Her family and past history are negative. Patient has a neurotic temperament. Her present illness is attributed to an injury to her knee from the horn of a cow fourteen years ago. The acute onset occurred one year ago, without preceding cause, with occasional trouble since. Patient has pain at times, moderate swelling, complete extension being impossible, with locking at intervals occurring in position of flexion, on which occasions patient has limped for several hours. Function is otherwise good, but there has been no improvement. The outside of the left knee-joint is involved. There is a slight swelling below the patella, and the left knee is 1 cm. larger than the right. No redness and motion to within 10° of complete extension. The swelling is soft and boggy on palpation and there is a small area of tenderness over the swollen portion. On February 13 an incision was made on the outer and inner aspect of the left knee. The capsule was not thickened and no fluid or fibrin appeared. One large fatty mass of fringes filled the entire lower portion of the joint cavity, loosely attached throughout to the synovia in shape an irregular lobulated mass 5 cm. in greatest dimension, with an abundant blood supply. The mass was of a yellowish-red in color and soft and yielding. The growth was dissected off the synovia. Considerable hemorrhage occurred but ligatures were not used. Hot water irrigation was tried and the capsule closed with silk. No drainage and a plaster dressing was applied. The general postoperative condition was good, and the stitches were taken out in eight days. The patient was at once manipulated and bandages and applications were used. Swelling, pain and redness appeared and persisted. On March 5 an incision was made over the outer aspect through the capsule, and 150 cc. of clear, straw-colored fluid evacuated. Healing took five days, after which there was a disappearance of symptoms and motion of the knee was rapidly regained. In May, 1903, the amount of motion was complete with no swelling or pain, and a perfect functional result.

Pathology.—Specimen consists of an irregular mass of tissue, 5 cm. in diameter and 1.6 in thickness, from lower portion of knee-joint, behind and to either side of patellar tendon. Growth was attached by numerous adhesions to synovia, not by a single pedicle. Very vascular, red to gray and yellowish in color, the tissue of a half fatty, half fibrous consistency, roughly lobulated, with several large tabs of yellow fatty tissue. Microscopical. A thick cortex of connective tissue, bordered by a single layer of endothelial cells, and marked round-celled infiltration of the outer portions. Thick-walled vessels very numerous. Going away from the periphery the connective tissue gradually gives place to adipose tissue, and persists only in irregular striated formation, while the very numerous vessels have extremely thickened walls and are often entirely obliterated.

Case No. 29. February 20, 1903. W. G. M., female, thirty-seven years of age. Diagnosis, rheumatoid arthritis. Family and past history of the patient are good. Rapid pregnancies (married at eighteen), and much care and worry were the exciting cause of her present illness. The onset occurred five years ago with pain and swelling, but no limitation or locking. Loss of function has been gradual, and there has been a gradual extension to other joints. Treatment has been general, medicinal principally, with hydrotherapy and diet. The knees, elbows, wrists, feet and shoulders are involved. Spindle-shaped swelling. Motion of knees was limited about one-third. On palpation soft, semifluctuant, and with slight tenderness on pressure. A lateral incision was made in both knees, and the capsule was found to be thickened and congested, with no excess of fluid and considerable fibrin. The fringes were numerous, generally attached to the synovial membrane, arborescent and small in shape, vascular, purple in color, and soft. Ligatures were not used, and the joint was irrigated with hot salt solution. Capsule was closed with silk. The wound was not drained, and a soft dressing was applied. Diet and general tonics were prescribed. The stitches were taken out in one week and daily manipulation after the first week with hot and cold douches were given. In May, 1903, the amount of motion was good, swelling slight, no pain, and fairly good functional result.

Pathology.—A dozen synovial tabs of varying size, the largest 4 cm. in length, narrow and with fringe-like processes, growing from the synovial membrane of knee-joint. Color varies from grayish white to reddish-white, while several are harder and contain much brownish pigment. Of fatty fibrous consistency and very irregular in shape. Microscopical. Cortex shows a thin lin-

ing of a single layer of endothelial cells. Within is a broad band of fibrous tissue densely infiltrated with small round cells, often arranged in clumps and whorls. This round-celled infiltration extends well into the interior of the section, but is finally replaced by loose connective tissue arranged very irregularly. Still farther from the periphery are numerous aggregations of fat cells, not, however, to the entire exclusion of the connective tissue. Very numerous vessels, whose endarteritic changes are very noticeable.

Case No. 30.—March 3, 1903. H. L. R., female, thirty-five years of age; nurse. Her family and past history are negative. The history of injury is indefinite.

The onset occurred five months previous, with a sensation of fulness and pain in left knee, followed by swelling. The pain, however, was not acute, but the swelling was symmetrical and quite marked. Extension was not quite complete and function was not much impaired. There was no improvement under strapping, and patient was in bed three weeks, after which crutches and bandage were used. Patient was a neurotic, well-nourished woman. The left knee-joint was involved, and had a swollen appearance on either side of the patellar tendon; swelling apparently of synovial membrane. Fifty per cent. of normal motion only permitted. Crutches and strapping having produced no improvement, patient was operated upon on April 18, 1903. An incision was made over the outer and inner aspects of the left knee. Fluid and fibrin were not found in excess, but there was a large fatty mass occupying upper and outer part of supra patellar pocket, with a similar condition on the inner side. There were also three or four small fringes about the patella and beneath the patellar tendon, attached to the synovia and quite freely movable. These were irregular, flat, very vascular, yellow to red in color, and of a soft and yielding consistency. The hemorrhage was slight. No ligatures. Silk was used to close the capsule; no drainage, and soft dressing was used. The stitches were taken out in one week and manipulation was performed during the third week. At the present date, May 13, 1903, function has not yet been restored to more than about one-half normal. The amount of motion is nearly a right angle. There is some swelling and pain on forcible flexion. And as yet the functional result is imperfect.

Pathology.—Three large irregular tabs from 3 to 2 cm. in length, composed of innumerable minute fringe-like processes, with twice that number of smaller synovial tabs, from a single joint. Attachments to synovial membrane by pedicles of various sizes, all very vascular, of varying color, ranging in same specimen from purple-red to gray and yellow, and of a distinctly soft, yielding, fatty consistency. Microscopical. The cortex shows a connective tissue basis, infiltrated especially on the extreme edge with numbers of small round cells, and interspersed with numerous blood-vessels and spaces filled with blood. In places this cortex is regular in outline, but sometimes it forms irregular tab-like projections, in which the infiltration is much more marked. The central portion of the tissue consists of irregular wavy bands of fibrous tissue separating clumps of fat cells, while numerous vessels appear, the smaller with occluded lumina. A thin cortical lining of flat cells with long nuclei is very apparent in this specimen.

Case No. 31.—March 18, 1903. C. H., female, aged sixteen years. Diagnosis, trauma. Her family and past history are negative. Her present illness was caused by a slight fall eight years ago, and a slight swelling occurred shortly after. The pain has always been very slight, but the swelling has persisted. There is no limitation or locking, although the patient is somewhat disabled and has walked lame at times. The trouble has been persistent. Aspiration was tried one year ago and only a small amount of fluid appeared. The left knee-joint was involved and was swollen 2 cm. more than the right. The arc of motion was normal. The swelling was symmetrical on both sides of the knee, fluctuating and with no redness. On either side of the patella there was a slight tenderness. On March 20 an incision was made on the inner and outer aspect of the knee. The capsule was normal, and one ounce of clear fluid was found. The operation revealed innumerable fringes, rarely over one cm. long, studding the entire inner wall of the joint, attached to the synovial membrane. These were delicate, pedunculated, dendritic outgrowths, very vascular, dark red in color and yielding in consistency. Considerable hemorrhage took place, vessels ligated. Hot water irrigation. The capsule was closed with silk; no draining was done, and a plaster dressing was applied. One week after operation stitches were taken out, and on May 4 right angle flexion was obtained by manipulation under gas. Very few adhesions appeared. The case is not yet discharged, because of adhesions in the joint, the result of injury to the joint membrane from scalding. At this date, May 13, about 15° of free voluntary motion, considerable thickening of the soft parts, but apparently good motion can be obtained.

Pathology.—Six irregular masses of tissue, the largest 3 cm. in length, each composed of a network of very delicate tongue- and club-shaped processes, reaching .5 in length, radiating from a pedicle attached to the synovia. Some of the smaller ones are less fine and delicate and tend to coarser lobulations. Reddish-gray in color, soft and yielding in consistency. Microscopical. Specimen consists of an irregular body cut in cross section with innumerable finger-like processes projecting from it, more or less tightly packed. These show traces of the original endothelial lining. Throughout is a small round-cell infiltration of varying degree, especially about what appear to be the remains of blood-vessels. The whole mass consists aside from these elements of a homogeneous mass of necrotic tissue which has undergone hyaline degeneration. No traces of connective or adipose tissue cells.

Case No. 32.—March 19, 1903. E. G., female, thirty years of age; occupation, housework. Diagnosis, acute arthritis. Her family and past history are negative. There is no known cause for her present illness. Her trouble is acute arthritis in the left knee. Eight years ago and four years ago she had attacks and she since has had a similar attack. The present attack dates nine months back. Pain at irregular intervals, often severe, is referred to the patella. It is accompanied by slight swelling, with no limitation or locking, but with grating and grinding of the joint on starting to walk after resting. At such times patient walks with a limp, which soon wears off. There has been no improvement in her condition. The left knee, which is 1 cm. larger than the right, is the joint involved. On the outer aspect of the patellar tendon is a swelling the size of a quarter of a dollar. The arc of motion is normal. The swelling is soft and boggy, with no redness or tenderness. There is one large lipomatous fringe on the outer aspect of the joint attached to the synovia by a broad pedicle. This is irregular and lobulated in shape, very vascular, yellow-red in color, and of a fatty and yielding consistency. Otherwise the joint is normal. The growth was excised. A moderate hemorrhage occurred. No ligatures were used. Hot water irrigation, capsule closed with silk. The wound was not drained and plaster dressing was used. The postoperative condition was excellent and the stitches were taken out after seven days. Manipulation immediately followed with bandaging. In one week 90° of flexion was possible. On May 6 normal flexion and extension with no swelling or pain, and an excellent functional result was procured.

Pathology.—A lobulated, yellowish, fatty growth, 5x3 cm., with a broad attachment to the synovial lining of the knee-joint. The attachment very vascular, and darker in color than the bulk of the tumor mass. Tissue of a gristly nature on palpation. Microscopical. A very thin cortex, often no more than a thin endothelial lining of a single layer of cells, but in places containing fibrous tissue with round-celled infiltration. The bulk of the tissue composed of adipose tissue, and numerous vessels of varying size in cross and longitudinal section, nearly all of them with obliterated lumina.

Case No. 33.—April 16, 1903. C. F., male, fifteen years of age; office boy. Diagnosis, relaxed joints. His family and past history are negative. There is no known cause for his present illness. His general condition at the time was poor. The onset was gradual and began seven months ago. Sharp, not constant, pain beneath the patella, especially when sitting. Patient noticed no swelling, and had no limitation or locking, but a sensation of crackling and slipping in knee. He can walk about. The symptoms have increased and are chiefly in the right knee. Both knees are involved and a slight swelling appears on either side of the patellar tendon. The arc of motion is normal. On palpation a sensation of slipping above and inside right patella. There is no tenderness. On April 8 an incision over the inner aspect of the knee. The capsule was not thickened and there was no fibrin or fluid. Four or five excrescences, the largest 1 cm. in diameter, were attached to the synovial membrane. They had a broad base, tapering to a blunt point, were lobulated, rich in blood, of a red color, and firm and fibrous. These fringes were excised with a slight hemorrhage. A few small vessels were tied with ligatures, and hot water irrigation was used and the capsule was closed with silk without drainage. Plaster dressing was used. The general postoperative condition was excellent and the stitches were taken out in eight days. Immediate manipulation was given and function was restored in one week. In May, 1903, the amount of motion was complete, with no swelling or any pain, and a perfect functional result.

Pathology.—Three small tabs from synovial surface of knee-joint, the largest 2 cm., the smallest 1 cm. in length, attached to membrane by broad base, and tapering outward to a point. Slightly lobulated. Of gray-red color and fatty-fibrous consistency. They projected prominently from surface of membrane. Microscopical. A thick cortex of connective tissue densely infiltrated with small round cells, the enclosing membrane not apparent. Numerous small thick-walled vessels. Within this layer is a layer of normal connective tissue which as it goes inward becomes more and more infiltrated with fat cells. Throughout this inner portion numerous thick-walled vessels running outward toward the periphery and surrounded with varying amounts of connective tissue. Numerous small vessels also present, often with occluded lumina.

Etiology.—Local tissue changes are effected in many different ways. In the condition here being considered, it would seem that the causes might be classified under the heads of (I) traumata, (II) infections, and (III) diathetic conditions.

1. Trauma.—Under the head of traumata are to be considered (1) direct blows and injuries to a joint and (2) indirect injuries, the consequence of strain to the joint from faulty position resulting in impairment of function. Traumata also result from within the joint itself, as when (3) a semilunar cartilage becomes partially detached, causing impairment of the function and, in some cases, direct violence to the synovial membrane (*e.g.*, Nos. 19 and 23). (4) Loose bodies in a joint, the so-called joint "mice," are capable of causing synovial irritation. (5) Forcible wrenches or lacerations of the ligaments of the joints (either the supporting external or the internal), weaken the joint, cause a relaxation of the ligaments, impair the function, and may thus cause the villous hypertrophy. (6) Flat and pronated feet, by causing strain to the internal lateral ligaments of the knee, are common causes of congested or hyperæmic knees, particularly in stout and flabby individuals, usually women. This condition is not uncommonly an accompaniment of the early convalescence from the confinement of pregnancy (*e.g.*, No. 12), and is also occasion-

ally met with at puberty in rapidly growing but sickly children, where there is much muscular and ligamentous loss of tone. We have also observed it in a young woman in whom there was some knock-knee and elongation of the patellar tendon. This was accompanied by considerable relaxation of the capsule of the knee-joint and thickening of that portion of it on either side of this tendon at the level of the line of the joint. Fibrinous clots cause sufficient trauma to irritate the synovia.

II. Infections.—Among infections first of all should be placed (1) tuberculosis. Some tuberculous joints show it more than others. As a rule, those in which the process has shown itself primarily in the soft structures of the joint rather than in the bones illustrate villous hypertrophy most decidedly. Usually, a tuberculous condition can be readily diagnosed clinically, and the aid of the microscope is rarely necessary. The difficulty of the histological diagnosis of these fringes has been demonstrated once in our experience where excision of the knee was performed following a pathological diagnosis of joint tuberculosis. The subsequent history made the diagnosis of joint syphilis much more probable (see Case 2). It has been shown occasionally that tuberculosis has grafted itself upon an ordinary hypertrophied fringe, which has evidently been pre-existent to the tuberculosis. (2) Gonorrhea, and probably other infective processes, cause villous hypertrophy. The writers have seen this in two cases here reported, namely, Nos. 21 and 22. In the more rapidly developing inflammatory conditions there is not as much villous enlargement as in the more chronic processes, probably because the invasion of the synovial membrane with such numbers of round cells prevents the folding up of the membrane, and the vascular changes are not so conspicuous as in the subacute processes heretofore mentioned. (3) Syphilis. The extensive hypertrophy of the synovial membrane due to syphilis has been mistaken both before and after exploration of the joint for rheumatoid arthritis. In one of our cases the correct diagnosis was arrived at when, one and one-half years after the arthrotomy, the tissues of the knee broke down and typical syphilitic ulcerations appeared. These cleared up with great promptness, and the swelling of the knee almost disappeared under large doses of the iodide of potassium (*e.g.*, 2 and 6).

III. Diathetic.—Under this head we have rheumatoid arthritis and osteo-arthritis. By the former we mean that polyarticular joint affection of the young adult which is characterized by spindle-shaped swellings of the joints affected, thickening of the joint capsule, and atrophy of the cartilage and bone. By osteo-arthritis we mean that polyarticular affection, usually of later adult life, characterized by hypertrophy and lipping of bone and cartilage, causing what is known as Heberden's nodes when the terminal phalanges are involved, and morbus coxæ sensilis when the hip is involved. Both of these diseases are accompanied by great villous hypertrophy of the synovial membrane, rheumatoid being much the more common.

In several of the cases here reported this was the etiological factor, namely, Nos. 5, 8, 9, and 29. That osteo-arthritic joint involvement, due at times to a general diathetic condition, but often wholly or in part to local trauma, may be a direct cause of villous hypertrophy, is illustrated by Case No. 7. The patient had a bony spur, evidently the direct result of an injury in football. This spur was surrounded by a villous hypertrophy. Removal of the spur and fringes certainly produced a complete cure twelve years after the original injury.

Clinical History.—The joints most frequently affected with these forms of arthritis are the knee, the shoulder, the ankle, and the hip. Of these the knee is most frequently involved, probably on account of its exposed position, its function in the weight bearing of the body, and the nature of its internal anatomy. Its exposed situation makes it liable to external trauma. Its function in the weight-bearing makes it liable to strain, and its internal mechanism is of a nature to be easily deranged. To a less degree these reasons apply to the other joints which have been mentioned. Depending upon the etiology of the arthritis in question, we find the type to be either monarticular or polyarticular. In cases following trauma, either direct or indirect, the lesion is monarticular, except where the etiological factor is bilateral in its distribution, such as pronation of the feet, relaxed knee-joint ligaments, etc.

Of course, where the hypertrophy of villi is due to toxic or inflammatory agents circulating in the blood, or to metabolic disturbances, affecting the general processes of the body, one would expect to find a polyarthritis, and this is usually the case. In looking over the history of these cases, it is noticeable that a considerable period of time has passed since the beginning of the trouble. This is particularly true of the traumatic cases. In these an interval of years rather than months or weeks is the customary rule. The explanation of this is probably that, until fibrous changes of considerable extent take place in these fringes, they do not simulate foreign bodies as they do subsequent to such fibrous change. In the early stage of passive congestion they are soft, and are readily disposed of in the act of moving the joint, and so do not give rise to symptoms other than swelling and a certain amount of discomfort and inconvenience upon first rising from a sitting position. Where some diathetic cause has been in operation, the fringe development has undoubtedly been so insidious that the patient cannot give a definite date to the onset of the joint symptoms. Here, then, we do not ordinarily find so long an interval between the onset of the trouble and the development of the joint fringes. In many cases there have been long intervals without symptoms referable to the joint. Such is usually the history where the primary cause was a trauma, giving rise to symptoms which were more or less temporary, with subsequent secondary traumata and lighting up of fresh symptoms. The symptomatology of this form of arthritis is often very indefinite, and

readily accounts for the lack of attention hitherto paid to the condition. There is sometimes an immediate onset of symptoms directly associated with the trauma, but more usually the symptoms which are due to the fringe are distinctly different in the mind of the patient from those which resulted from the trauma itself. The symptoms which are directly referable then to the presence of the fringe are these: a more or less frequently recurring synovitis which perhaps never wholly disappears, a sensation of pinching something between the component bones of the joint in the act of walking, at first occurring rarely, but becoming progressively a more or less constant symptom during the use of the joint. There is also a more or less local swelling of the membrane of the joint, usually of that portion which is below the patella and on either side of the patellar tendon. Pain is not ordinarily present when the patient is quiet. Sometimes this radiates down the leg almost to the ankle, and is usually of a sharp incisive character. The normal passive motion of the joint is not interfered with in flexion, and only occasionally is extension somewhat limited. When this occurs, it is usually due to the hypertrophy of those few villi which arise from the alar ligaments. Locking of the joint almost never occurs, as it does in the case of the dislocated cartilages. Although the patient is conscious of the presence of a soft body between the articular surfaces, he is usually able to flex or extend the joint at will. What has just been said regarding the symptomatology applies principally to the traumatic cases. Those which are due to a definite arthritis of toxic or diathetic origin differ in that the swelling is more symmetrical, is rarely or never confined to any one quarter of the joint, is accompanied much less frequently by a true effusion. Where the hypertrophy of the synovial membrane is general, the joint often appears to be filled with fluid. The patella seems to float, fluctuation is easily obtainable, and one is frequently surprised on opening the joint to find no excess of fluid. Under these circumstances one finds a very large mass of soft friable fringes, which protrude from the joint as soon as the capsule is opened. They look and feel in many cases like masses of small angle worms. In the cases dependent upon a general diathesis, as rheumatoid arthritis, contracture of the joints, spasm of the muscles, and other evidences of a true arthritis are usually found. Such symptoms do not commonly accompany the villous hypertrophy due to trauma. Measurements made will show an increase in the size of the affected joints which, in cases of traumatic origin, is usually either below the patella or above the patella only. In the other types the swelling is more diffuse, and the enlargement of the joint is noticeable throughout its entire extent. Pain on motion of the joint is not commonly noted, except in the cases where there is a definite arthritis of diathetic origin. Tenderness, localized over the fringes which are most readily palpable, is not uncommon, and is, in fact, usually present where the fringe is of any considerable size.

Differential Diagnosis.—In diagnosing this condition from others, few affections are to be considered. It cannot always be determined which of the several possible causes is responsible for the trouble. Usually, in the presence of any obvious joint disease, the explanation of existing fringes is not far to seek. Defects in the standing position of patients productive of joint strain at the knee should be looked for to explain symptoms such as have just been enumerated. The history of trauma should be inquired into. It has usually been sufficiently severe to attract attention. The general conditions occurring in weak and debilitated people which cause general and local muscular relaxation must also be borne in mind.

With these general observations it remains to consider what other conditions may cause these symptoms. Early synovial tuberculosis must be borne in mind. The patient's general condition in these cases is usually poor, as is also the case in rheumatoid arthritis. Tuberculosis, however, is monarticular, while rheumatoid arthritis is polyarticular in a large majority of cases. It is in these early tubercular cases that explorations are indicated after other methods of diagnosis have been exhausted.

The history of a gonorrheal affection accompanied by definite joint involvements is suggestive, but a simple history of a gonorrhœa at some more or less remote period is of no significance. It also should be borne in mind that the infective arthritic processes are possible excitants to rheumatoid changes, and that such a history, with rheumatoid appearances in the joints on gross examination, may indicate the subacute or chronic state of an infective process, or the early stage of a rheumatoid. A histological examination would probably clear up such a diagnosis.

A dislocated or partially dislocated semilunar cartilage may cause confusion, and it is sometimes impossible to establish the diagnosis. As a rule, there is not the locking of the joint in a partially extended position in the villous hypertrophy, as there so frequently is in the case of the cartilage; and the history of the dislocated cartilage is suggestive.

The difficulty arises where the cartilage was but slightly displaced, and was not accompanied by the customary trauma. In three cases in this series there were found hypertrophied synovial fringes, evidently due to the derangement of the joint in consequence of a partially detached cartilage which had not been definitely diagnosed (Nos. 15 and 26). An habitually recurring synovitis will frequently be found to be due to the existence of a fringe or fringes. Any simple synovitis that cannot be explained away on some reasonable ground should cause suspicion. In this series is one case of intermittent hydrops that was full of well-developed fringes. The hydrops was not materially benefited for any considerable length of time by the removal of the greater part of the fringes, so that this condition was probably simply a coincidence in the process. Intermittency in the accumulation of a synovitis would

lead one to be rather less sanguine as to the probable benefit of an arthrotomy in a villous arthritis thus complicated, and should be borne in mind in the differential diagnosis. The cases in which malignant disease, as sarcoma, finds its starting point in the villi of a joint are so rare that they must be regarded in the light of medical curiosities. Of monarticular affections osteo-arthritis not commonly causes a villous arthritis. This is usually accomplished by the trauma inflicted upon the joint by the osteo-arthritic spurs, which develop about the condyles and along the border of the patella. These irritate the synovial membrane, and cause the development of fringes in their neighborhood. These spurs can usually be recognized on palpation and almost always in the skiagram.

Treatment.—The treatment varies with the causation of the arthritis. Very many of the early cases, when caused by pronated or flat feet, where the condition in the knee-joint is that of a passive hyperemia due to the malposition, are promptly and permanently cured by resort to a proper support for the foot. This must be worn for a considerable time after the subsidence of the joint symptoms. Adhesive plaster strapping tightly applied over the front and sides of the knee to compress the synovial membrane and lessen the chance of its being crowded together and pinched by the action of the joint is helpful in relieving the symptoms and causing the fringes in some cases to shrink up. This is particularly true in the cases where the condition results from general loss of tone in the joint capsule or from faulty attitudes in standing and walking.

Where the villous hypertrophy is due to some diathesis, such treatment can be only palliative. In this last class of cases, however, the presence of the fringes is a source of irritation and injury to the joint, and here, as in all other cases, where strapping, bandaging, and correction of existing causative defects in the feet are not effective, operative measures should be taken. Prolonged fixation in plaster or other splints does not accomplish any permanent good, and long-continued conservative treatment is not to be recommended. The fact that the individual and not simply the joint is being treated should not be lost sight of, and general tonic treatment, massage, and exercises are indicated in the appropriate cases. In the osteo-arthritic cases, of course, any stirring up of the joints where spur formation is causing the villous hypertrophy is to be avoided. This applies to massage as well as to exercise, and here partial fixation in removable splints of leather is at times effective in quieting down the process. In such conditions as muscular and ligamentous laxity, some stages of the rheumatoid process, and the later or convalescent condition of the primarily infective cases, massage, exercise, and such measures are effective, and should be used. Here, also, local stimulating treatment by means of the alternate douche of hot and cold water is very beneficial. In the more acute stages of the rheumatoid fringes, hot fomentations and rubber dam worn next the skin at night give the patient more comfort, although the nature of their therapeutic value is uncertain. Dry heat at high temperatures is of little value.

The therapeutic treatment of the underlying condition in those cases, caused by rheumatoid and osteo-arthritis, is most unsatisfactory. The acute rheumatic remedies should be used very sparingly, and never continuously. The same is true of the sedatives and soporifics. Careful nursing, fixation of the affected joints during the acute stage, and general tonic treatment give the best results in the long run. Diet should be plain, but plentiful, and restricted only by the patient's capacity for digestion. These details are gone into here for two reasons. Many practitioners who have overlooked the fringes, because they have not examined their patient's joints, regard the symptoms arising from these conditions as rheumatic, and treat them accordingly The result is that the patient's general health becomes undermined, and if, perchance, the villous arthritis is rheumatoid in character, the worst consequences are to be expected. On the other hand, rational therapeutics has its place, and should be thoroughly followed.

Operative Treatment.—Failing in the relief of these conditions by the before-mentioned conservative measures, we have to consider the radical or operative procedures. These are to be undertaken when other treatment has been tried and failed, or when the condition is such as obviously could not be relieved by conservative methods. It offers the quickest and, in the long run, the most satisfactory results. It is not attended by any particular risk, and is rational in every way, especially in the cases of traumatic origin. Under the modern technique one thinks very little of the risks of infection. In this series of cases this has not occurred. With proper after-treatment there is no serious probability of a stiff joint, and restoration to normal motion and complete function is usually speedy and uncomplicated. There is practically no risk of weakening the joint because of the incision through its fibrous envelope, and there have been, so far as observed, no late sequelæ which tend to make one hesitate to operate. Where the villous arthritis is simply an evidence of a chronic general disease, the purpose of the operation differs from that in the cases in which the hypertrophied villi are the result of an injury or of some acute inflammatory process. To reach these fringes in the knee-joint, which is the joint most commonly explored, it has been found that a lateral incision about 5 to 6 cm. long over the inner aspect of the joint, extending a short distance below its lower border, affords an opportunity to investigate a considerable portion of the synovial membrane by direct inspection, and what cannot be seen can be explored by the finger. Familiarity with the "feel" of the fringes makes one quite expert in detecting them where they cannot be seen. If in this way it is demonstrable, or presumable even, that more fringes are situated on the outer side of the joint, a similar in-

cision is to be recommended over that aspect. In extreme cases, usually due to some diathesis, where there is extensive hypertrophy of the villi, we think that it is reasonable and proper to connect the two incisions which are usually made for exploratory purposes at their lower extremities, and in doing this to divide the patellar tendon close to its insertion into the lower border of the patella. On turning back the flap, the entire joint cavity is exposed, and the dissection of the villi is much more easily accomplished. The objection to this procedure is that the convalescence is necessarily prolonged because of the six weeks or more of immobilization of the knee required after division and suture of the patellar tendon. In several cases where joint tuberculosis has been diagnosed early excision of the parts of the synovial membrane attacked by the disease has been attempted, and this incision has given admirable opportunity for the removal of the disease, while the functional results have been extremely good. This, too, in spite of the fact that it was necessary, because of the nature of the disease, to protract the convalescent treatment very materially.

The removal of these villi is not ordinarily accompanied by any recurrence because the cicatrization of the denuded portion of the capsular surface causes the entire membrane to shrink, and scar tissue does not readily lend itself to villous hypertrophy. Thus, even in the diathetic cases, where the removal of the fringes is performed for the sake of freeing the joint from their irritative action, good results may be expected both locally and generally, through the improved function of the joint and the consequent influence which this improved function has upon the general condition of the patient.

Sometimes, on account of the vascularity of these fringes, some difficulty is experienced in checking the hemorrhage. It is impossible to ligate all the small bleeding vessels inside the joint, and the cauterizing effect of hot water is necessary. The only bad result attributable to our technic which has occurred in this series of cases was one in which the water supplied was so hot that the synovial membrane was scalded, and sloughing took place. This case is still under treatment, and we are trying to secure motion in the joint with apparently satisfactory results.

The capsule is closed with interrupted silk sutures, usually four or five in number, placed some distance apart, so as not to close too completely the synovial capsule. They also include the fibrous tissue. The skin incision is closed with either interrupted silkworm gut or subcutaneous continuous silver. In the majority of cases silkworm gut was used. In regard to dressings we have had experience both with fixation and with soft dressings alone. All our early cases were put up first in plaster-of-Paris dressings, which were kept on for at least a week.

In several recent cases immobilization was not practised, a soft dressing only being used. Joint effusion was not more marked.

(To be Continued.)

ECLAMPSIA HEMORRHAGICA. REPORT OF A CASE.

BY RALPH WALDO LOBENSTINE, M.D.,

RESIDENT PHYSICIAN SLOANE MATERNITY HOSPITAL, NEW YORK.

A REPORT of this case may prove of some interest (1) Because of the uncertain etiology of the disease; (2) because of its severity; and (3) because of the rarity of this type of eclampsia (three cases only in the last 128 cases of eclampsia in this hospital).

Inasmuch as the etiological differences between eclampsia and nephritis with uremia remain still unsettled, it is as yet impossible to say whether or not the hemorrhages that occur in the two diseases are due to the same factors.

With reference to the essential pathological lesions of eclampsia, we know that there are to be found in the various organs of the body small areas of necrosis, due to thrombi in many of the smaller blood-vessels; but we do not know the true nature of the substance which, circulating in the blood, gives rise to these thrombi. The organs chiefly affected are the liver, kidneys and brain; of these, the liver seems to be the most constantly affected. In eclampsia hemorrhagica, likewise, the liver appears to be more often involved than any one other organ, as jaundice is to be found in the great bulk of the cases. The jaundice often manifesting itself before the appearance of the first hemorrhage. On autopsy, the liver presents to a marked degree, the appearance of acute yellow atrophy. This type is considered to be due to a greater toxicity of the blood, than the former, the hemorrhages indicating a greater impairment of the walls of the capillaries.

History.—The patient was a primipara, aged twenty-two years, 6½ months pregnant. She gave no previous renal history; her health had always been excellent, up to three days prior to her entering the hospital. During these three days she suffered from headache, scotomata and nausea.

Examination on Admission (September 22, 1902 at 1 P.M.).—(*a*) Subjective symptoms. Headache, scotomata, nausea; (*b*) objective symptoms. The patient appeared but moderately poisoned. There was slight edema of the ankles and feet. The heart and lungs were normal. The pulse was 98, of high tension, full and bounding. The abdomen showed the usual signs of a six to seven months' pregnancy. By vaginal examination, the cervix was found to be soft, fairly elongated, and to admit one finger throughout. The urinalysis report was acid; sp. gr. 1.026; albumin 30 per cent. by vol.; many casts of all varieties.

Course of the Disease.—Antepartum (September 22). Despite medical treatment, the patient had a very severe convulsion, about three hours after admission. Labor was, therefore, at once induced by means of a No. 1 Voorhees bag. This was expelled about two hours later, the patient being, in the meantime, kept under the influence of chloral and nitroglycerin. At 7 P.M. an ac-

couchement forcé was performed by Dr. Edwin B. Cragin. The fetus was non-viable.

Postpartum (September 22). The patient stood the operation well and seemed to improve considerably after the delivery. There was neither headache nor nausea. She slept quietly most of the night. When awake nourishment was well taken. Temperature 99.8° F.; pulse 84 with less tension; respiration 24.

(September 23). Severe frontal headache; moderate nausea and vomiting; restless but no convulsions. Nourishment fairly well taken. Lochia moderate, red; temperature 99° to 97.8° F.; pulse 80 to 100, of moderate tension; respiration 20 to 30; urinalysis, acid; sp. gr., 1.016; albumin, $^{2}/_{10}$ per cent. by weight; urea gr. 3 to ℥i; many hyaline and granular casts; total quantity, 50 ounces.

(September 24). Nauseated; vomited several times *dark brown fluid;* abdomen distended, painful and tender. Tenderness especially marked in the right hypochondrium. Moderate **jaundice;** edema of the face; *expectorated bright red blood* in the evening, and complained of a severe pharyngitis. Pharynx congested. Temperature, 98.4° F.; pulse, 110 to 120, of high tension; respiration, 20 to 28. Lochia moderate, dark red. Urinalysis, acid, 1.018; albumin, $^{6}/_{10}$ per cent. by weight; urea, gr. 2 to ℥i; moderate number of hyaline, granular and epithelial casts. Total quantity ℥ 24+.

(September 25). Frequent vomiting of *dark brown fluid;* abdomen somewhat less distended and tender; fair result from strong catharsis; jaundice the same: *many petechial spots on trunk and extremities;* pharynx very painful; submucous retropharyngeal hematoma. Some general improvement toward evening: temperature 98° to 100.2° F.; pulse, 130 to 120, irregular at times and of moderate tension; respiration, 36 to 30; lochia moderate, dark red. Urinalysis, acid, 1.026; albumin, $^{5}/_{10}$ per cent. by weight; urea, gr. 8 to ℥i; many hyaline and granular casts; total quantity, 61 ounces+.

(September 26). No headache; less irritable and restless; pharynx the same; *vomited dark brown fluid;* abdomen moderately distended and tender; no enlargement of the liver. Temperature, 100° to 98.4° F.; pulse 128 to 100, of low tension; respiration, 30 to 24; lochia, moderate, dark red; urinalysis, acid, 1.024; albumin, $^{1}/_{10}$ per cent. by weight; urea 7½ gr. to ℥i; casts of all varieties; total quantity, 69 ounces.

(September 27). General condition apparently improved; pharynx improved; no vomiting; *blood-stained fluid defecation.* Temperature, 98.4° to 100.2° F.; pulse, 118 to 114; respiration, 20; lochia, moderate, dark red. Urinalysis, acid, 1.026; albumin, $^{2}/_{10}$ per cent. by weight; urea, gr. 8 to ℥i; fewer casts; pus and epithelial cells; total quantity, 52 ounces.

(September 28). Nauseated, *vomited dark red blood* several times; severe epigastric pain; abdomen tender and somewhat distended; jaundice the same; no headache; restless. Temperature 100.6° to 101° F., pulse, 124 to 112; respiration, 28 to 38; lochia, moderate, dark red; urinalysis; acid, 1.024; albumin, $^{2}/_{10}$ per cent. by weight; urea, gr. 9 to ℥i; casts decreasing; total quantity, 53 ounces.

(September 29). Jaundice less; pharynx no longer painful; hematoma decreased in size; *tarry stools;* general improvement toward evening. Temperature, 100.4° to 100.6° F.; pulse, 120 to 110; respiration, 28. Lochia moderate, dark red. Urinalysis, alkaline, 1.022; albumin, $^{1}/_{10}$ per cent. by weight; urea, gr. 8½ to ℥i; total quantity, 56 ounces; very few casts.

(September 30). No headache; no restlessness; cheerful; no abdominal pain and only slight distention; vomited *small amount of blood;* stools normal. Lochia moderate, dark red, with odor. Temperature 100.8° to 101° F.; pulse, 112 to 118; respiration, 26 to 30; urinalysis, acid, 1.024; albumin, $^{2}/_{10}$ per cent. by weight; urea, gr. 9 to ℥i; total quantity, 25 ounces; only few casts.

(October 1). Marked general improvement; jaundice and petechial spots have almost disappeared; abdomen soft; nourishment well taken. Lochia moderate, yellow, with odor (slight). Temperature, 101° to 99° F.; pulse, 110 to 120; respiration, 28 to 32.

From this time on the patient made an uninterrupted recovery. There were no further hemorrhages. The albumin and casts gradually disappeared. The temperature, which was in part due to some slight uterine absorption, gradually dropped to the normal. The patient was discharged on October 19, in very fair condition.

To Summarize.—We find an eclamptic with but one convulsion, but with hemorrhage into the skin, pharynx, stomach, liver and intestine, accompanied with jaundice.

Brief Outline of the Treatment.—For the convulsive period; sedatives, arterial dilators, accouchement forcé. For the general toxemic condition, hydrotherapy and stimulation; for the hemorrhage, suprarenal extract; during convalescence, tonics.

WHO MAY BENEFIT BY ALTITUDE TREATMENT?*

BY J. N. HALL, M.D.,
OF DENVER, COLO.

My excuse for presenting this rather timeworn subject is that the physicians in the Rocky Mountain region still see a considerable number of patients sent from other localities who might better have remained at home. In my twenty years' experience here, I have noted continually greater care in the selection of cases to be sent here by physicians in the East. I write this with the hope of doing my small share to bring about a further improvement.

It is not only a lack of trained judgment upon the part of a physician which may lead to the

*Presented to the American Therapeutic Society, Washington, May, 1903.

sending of unsuitable cases to the West. The very great majority of the patients we see have had the benefit of careful examination and discriminating estimate of their condition by excellent practitioners. But a few have been advised, not, to be sure, by men of the character of our own membership, to go to the Rocky Mountains, without the trouble even of stripping the chest for examination. I have seen cases of heart disease, asthma, and chronic bronchitis, sent to me with a diagnosis of tuberculosis. These are the patients who say: "Why, Dr. Blank did not ask me to remove even my coat when he examined me." Such carelessness is criminal.

Certain patients with advanced lung trouble must have been sent with a certain knowledge that they could not live a month. Five days ago I saw such a one who died on his fifth day in Colorado who had not even been told that he had tuberculosis. My statement to his sister that he had but a few days to live came to her like a thunderbolt. She stated that they had always feared that he might contract tuberculosis, but their physician had told them that he had only a slight bronchial trouble.

My own explanation of such a mistake, and it is far too common, is as follows: The patient complains of a cough, and receives a cough mixture without any but the most perfunctory examination of the lungs. As the cough progresses a relative asks if it is possible that the case is one of phthisis. The doctor assures him that "it is only a bronchitis," and "that it will be better when the weather becomes settled." Meanwhile, the patient, who ought to be at rest and upon a suitable diet in a proper location, continues, as did the one just mentioned, to work in an ill-ventilated newspaper office. He finally becomes so ill that a change of diagnosis must be made or the patient sent away. I fear the latter course is occasionally the easier for this type of physician. I have repeatedly known their poor victims to be so ill upon arrival at the station as to preclude the possibility of sending them home alive. Proper examination, honesty and the most ordinary judgment would prevent these errors.

Of the conditions suitable for altitude treatment in this region, pulmonary tuberculosis is the most important, as all must recognize. The percentage of recovery depends more upon one factor than upon all others combined, namely, the stage of the disease. A large percentage of physicians recover from tuberculosis here. It is accounted for solely by the fact that the doctor with a beginning cough falls early into expert hands, and is sent away with the first suspicion of the true nature of his disease. If all patients with cough were sent to the mountains upon the appearance of a few crackles in one apex, without waiting for dulness to appear, and even before a positively bacillary examination was obtained, there would be more well men and fewer diagnoses of consumption. I know a score of physicians in robust health who have started West upon a week's notice and recovered. Had they waited the advent of well-marked dulness, I should have known fewer of them. The urgent need in the treatment of tuberculosis of the lungs is not, in our present age, cod liver oil, not creosote, nor yet a curative serum, but early diagnosis. Given this, without even waiting for too absolute proof of its correctness, if the first bacteriological examination be not positive, and we may expect 90 per cent. of recoveries. As infiltration is added to the catarrhal process the diagnosis is easier and surer, but the prognosis is proportionally less favorable. After considerable dulness and even excavation occur at one apex, there is a fighting chance of arrest, and a good chance of delayed progress. Involvement of both lungs, except it be purely catarrhal, generally precludes hope of complete arrest.

The predominance of the fibroid element in the tuberculous process is certainly favorable as to slowness of advance, but cases with this characteristic rarely attain the complete arrest so often seen in the early catarrhal cases. I see many of these cases following pleurisy with effusion which go on for many years, always coughing and expectorating a little, with very gradual loss of weight, with bronchiectasis, and perhaps, finally, apical cavity formation. These cases have many years of useful life here, beyond what they would have enjoyed in a less favorable climate.

There is one variety of phthisis little dwelt upon in the text-books which should be mentioned, for I believe the cases last much longer here than in lower lying regions. I refer to the type seen in certain young adults with moderate loss of weight, practically normal temperature, with little or possibly no appreciable dulness, but with constant cough, considerable expectoration containing abundant bacilli, great dyspnea, and upon examination, lungs bristling with fine moist rales. I have in mind three such cases, each of three to ten years' duration, with such slow downward progress that it can scarcely be noticed. I have never observed this type in New England, and doubt if it could exist there for such lengths of time. The prognosis is so much better as to time than one would at first believe that they should be carefully separated from the ordinary type, and sent to the high dry regions. The dyspnea may be severe for a time, owing to the obstruction of so many bronchioles, but the disease process does not seem here to extend to the lung tissue as one would anticipate.

Persons with a bad family history of tuberculosis may well consider the advantage of moving permanently to a high, dry region before the advent of signs of the dreaded disease. In cases where the lung does not entirely re-expand after pleurisy with effusion, two reasons should counsel us to send them to a considerable altitude. Firstly, the rarer atmosphere favors the expansion of the crippled lung; and secondly, the development of tuberculosis is thereby directly rendered less likely. In addition, we have the general antituberculous effect of the climate, even

though the lung cannot re-expand because of adhesions.

I think there is no question that glandular tuberculosis progresses more favorably here than at sea-level. This opinion is certainly held by Dr. Leonard Freeman and other surgeons of Colorado who have had experience both here and in large cities of the East.

Many cases of asthma are permanently relieved in this climate. The less the association with asthma, or its twin evils, chronic bronchitis and emphysema, the greater the chance of such permanent relief. If, however, the emphysema be not extreme, or associated with weakness of the right heart, such cases may be safely regarded as favorable for altitude treatment. The well-known purity of atmosphere of higher regions does much more good than the decreased density of the air does harm, the relief of the spasmodic element and of the bronchitis being the striking features in bringing about the improvement.

Almost constantly in those who have lived for many years in our mountains one may observe an increased chest development virtually amounting to moderate emphysema. This is a compensatory process, because of the need of great lung surface. Its origin, however, should teach us that the improvement in asthma and chronic bronchitis in this region is in spite, if not on account, of the emphysema. On the plains of eastern Colorado the lesser altitude is more favorable for cases with decided emphysematous changes.

The complication of tuberculosis of the lungs by organic heart disease often causes difficulty in deciding where to send a patient. I think we shall generally be right if we respect most the predominant condition. If any material dyspnea be caused by the heart trouble, only an incipient tuberculosis would probably be susceptible of improvement in a high altitude.

I do not observe any especial difference in the behavior of valvular heart disease or myocardial affections at Denver from that at sea-level if compensation be good. If it be on the point of failing it is a risky experiment to send the patient to any great elevation. In such a patient, scarcely any condition is susceptible to improvement by altitude treatment.

Of late years a host of the victims of malaria from the South and Southwest, as well as those returning from our tropical possessions, seek recuperation in the Rocky Mountain region.

The anemia and enlarged spleen are commonly ameliorated rapidly, and the absence of further infection is of great advantage. In those recently from the South we occasionally see outbreaks of ague, and I have seen, since the Spanish war, the only two pernicious malarial paroxysms that I have ever heard of in Colorado, both in newcomers. I know of no condition more certain to be benefited by the climate of the Rocky Mountains than the one we mention. I have seen many soldiers returned from Cuba and the Philippines who had suffered from the graver forms of ague, and practically all recovered completely, though often with severe relapse. This is also, so far as I know, the general opinion of the medical officers of the army.

The well-recognized increase in the number of red cells and the percentage of hemoglobin in certain anemias, upon removal to higher altitudes, is sufficient ground for the belief that the secondary anemias at least do rather better there than elsewhere. I know of no such influence in pernicious anemia. It certainly occasionally develops in those who have long lived in Colorado. I have recently seen a case in a man who has resided there for more than thirty years.

Certain cases of hay fever do wonderfully well with us, but some atrocious cases develop in the farming regions of Colorado, especially, perhaps, from the cottonwood tree and from alfalfa.

Those exhausted by prolonged summer heat find in the cool bracing nights of the mountains a tonic which cannot be obtained at home.

I know of no especial influence upon most other diseases aside from those of the nose, throat and ear, which others are more competent to discuss.

MEDICAL PROGRESS.

MEDICINE.

Syringal Hemorrhage into the Spinal Cord.—The etiology and the symptoms of this interesting but happily rare condition, is presented by Sir William Gowers (Lancet, Oct. 10, 1903), and several of his most interesting cases cited. Perhaps the most characteristic sign presented is the pain, which is described as being so severe that it makes the patient shriek with agony, the legs feeling as if they were being broken across. The bulk of the pain, however, is locally over the spine, the referred pain being entirely secondary as regards degree. Such pain as this does not occur in simple myelitis. If the blood escapes into a cavity of considerable vertical extent, there is not much erosion of the cord at the seat of the hemorrhage until the cavity is filled. It is probable that the cavities into which these hemorrhages take place, may be in many cases regarded as congenital. Some authorities, however, differ from this. It is easy to understand how hemorrhage may readily occur into these preexisting cavities. They are irregular in position and in size, and therefore in their relation to the vessels. The adjacent gliomatous tissue which surrounds them seems to be readily broken down by the fluid they contain. Adjacent vessels are imperfectly supported and may easily give way. Furthermore this gliomatous tissue is extremely vascular and may be a source for the hemorrhage, without any reference to the larger vessels. The symptoms, therefore, will vary rather directly as the congenital spaces of the cord are greater or smaller and are surrounded by a more or less vascular area. Inasmuch as these spaces are distributed along the posterior cornua, it must be remembered that if distended by blood, they may compress the lateral columns. And if it extends forward to the central region, it may compress the anterior horn. To differentiate the condition from a cerebral lesion, it is important to note that the latter never causes complete paralysis of the arm without any affection of the face or leg. The sternomastoid is weakened on the side opposite to the paralyzed arm, not on the same side. The most important therapeutic point is to give absolute rest in every

case of sudden spinal palsy. This is especially important when pain suggests a hemorrhagic cause. Every effort should be made to reduce the blood pressure in the spinal cord. To this end the spine should not be the lowest part. Therefore, the posture of the patient is of great importance. In all cases where there has been an escape of blood, the influence of gravitation for good or evil is too often overlooked. Hence, in the case under consideration, the prone position should be maintained, or, if possible, the patient should be placed in a sitting position. Posture is of the utmost importance in the treatment of all acute affections of the spinal cord.

Epidemic Pneumonia.—An epidemic of lobar pneumonia is described by F. SPAET (Münch. med. Woch., Sept. 29 and Oct. 6, 1903), which was peculiar in that it occurred in a small country town where the hygienic conditions were excellent. Within two months 13.9 per cent. of the inhabitants had been affected. The course and physical signs were typical and in general severe, yet fatal cases and complications were rare. Epidemics of pneumonia are not common and generally occur where many people are herded together or else are secondary to influenza and then more irregular in type and marked by severe pains in the limbs and vomiting. One is forced to conclude that genuine lobar pneumonia is occasionally a contagious disease, though the conditions which enable it to spread are still unknown.

Occurrence of Bacteriuria.—The occurrence of idiopathic inflammation of the bladder in children is certainly rare when one considers that the prominent symptoms—tenesmus with discharge of small amounts of urine free from blood and pus—are rarely overlooked. D. CNOPF (Münch. med. Woch., Oct. 6, 1903) points out that autoinfection plays a prominent part, for the majority of patients were girls suffering from enterocolitis, where contamination of the genitals was hardly avoidable and the short urethra facilitated infection of the urinary passages. With boys, the explanation is somewhat more difficult, but it has been shown that bacilli can readily wander through lesions of the rectum into the bladder. Infection by way of the blood is not yet absolutely proven, though colon bacilli have been found in the circulating blood of infants suffering from enteritis. A bacteriological examination of the bladder-contents in such cases may show the presence of colon bacilli, even if there are no vesical symptoms. There must be some concomitant weakness of the bladder-wall induced by cooling off of the body, retention of urine or general intoxication, especially if the kidneys are much diseased. The symptoms may be very mild or very severe; in the latter case there is high fever, chilliness, nausea and constipation. The abdomen is exceedingly tender and burning, saturated urine is constantly voided in small amounts. On examination it contains albumin, mucus, pus, epithelium and even red blood cells. The colon bacillus, exceptionally the *Bacterium lactis aerogenes* or the *Diplococcus pneumoniæ* are found in large numbers. The condition may run its course in one to two weeks, but obstinate recurrences may follow. Ofttimes an obscure temperature-curve is due to this bacteriuria. Serious complications, such as urethritis, pyelitis, nephritis or uremia hardly ever occur in children, but treatment should be prompt and energetic. Urotropin internally is harmless in children and efficient, though it must often be given for weeks. Bladder irrigations with dilute antiseptics are of course in place.

Acute Leucemia.—The subject of this rather extensive report, by A. M. YANOUSHKEVICH (Prakt. Vrach, Aug. 23 and 30, and Sept. 13, 1903) began to complain of severe pain in the throat, general malaise and loss of appetite; the pain passed off in a few days, but the weakness increased rapidly compelling the patient to give up his work. A week before admission he began to suffer from cough, dizziness, sweating and slight fever; in a few days thereafter there appeared a swelling under the upper lip, and an offensive odor from the mouth. There were no ecchymoses or petechiæ anywhere on the skin; the various glands but slightly increased in size. There were three ulcers on the reddened swollen gums. Auscultation of the arteries gives a distinct anemic murmur. The spleen is enlarged. Microscopic examination of the blood shows a marked increase in the white blood corpuscles, while the red corpuscles are of various sizes; there are also a few poikilocytes. The first count gave 52,500 white and 1,540,000 red corpuscles, and 4.86 gr. hemoglobin (Glan's method). The urine contained a trace of albumin; otherwise normal. The temperature kept gradually increasing; there occurred convulsions in the right foot, followed by convulsive twitchings of the head which lasted for two minutes. The ulcers meanwhile coalesced, forming a large, offensive, painful wound; odor from the mouth intolerable. The glands began to swell, the pulse became weaker, 156, respiration 38, condition of patient, comatose or delirious; complains of blindness, general hyperesthesia; the last count of blood corpuscles showed 165,000 white and 740,000 red (1:4.5), hemoglobin 2.1 gr. Patient died on the tenth day of his admission to the hospital with symptoms of severe dyspnea and cardiac weakness. The autopsy fully verified the antemortem diagnosis of leucemia; the most important alterations were as follows: Gangrene on the inner surface of the entire upper lip and part of the gums; fatty degeneration of the cardiac muscle; enlargement of various glands with hemorrhages into their tissues; lymphomata in many of the organs; enlargement of the spleen to almost double its normal size. Enlargement of the intestinal follicles as well as of Peyer's patches. Alterations in the bone marrow of the sternum and ribs, and so on. It is interesting to note in connection with this case the absence of a very important symptom of such a condition, namely hemorrhagic diathesis; the author is inclined to ascribe this absence either to some special individual characteristic of the patient's system, or to the character of the poison which in this case failed to exert any deleterious effect on the endothelium of the blood vessels.

Question of Meat Diet in Nephritis.—Some clinicians forbid meat in nephritis since this is rich in proteid and is apt to increase the percentage of albumin in the urine. T. R. OFFER (Centralbl. f. d. g. Therap., Sept. and Oct., 1903) shows, however, that this is based upon an erroneous calculation and that with a strict milk diet more proteid is often ingested than where a moderate amount of meat is allowed. Restriction of dark meat is still advocated by many, owing to the larger amounts of extractive matter present, which is supposed to irritate the kidneys. According to the writer's accurate chemical analyses however, the differences are so slight as to be of no practical value. When meat is roasted, a certain amount of extractive matter passes over into the sauce and this is more pronounced in the case of dark meat, so that beef-steak would really be more permissible than roast veal.

Condition of the Stomach in Tuberculosis.—According to A. ROBIN and E. DU PASQUIER (Bull. Gen. de Therap., Sept. 30, 1903), the stomach suffers in every stage of tuberculosis. In the earliest period one encounters hyperacidity most often. The patients will complain of pyrosis, acid regurgitations and a number of disagreeable sensations during digestion or five or six hours later. The symptoms are intermittent and there are even times when they will boast of an ex-

cellent stomach. The appetite is capricious, the tongue appears normal and constipation is not rare. Vomiting when present, is rather characteristic, in that it is not accompanied by nausea or pain. The hydrochloric acid rarely exceeds one gram to the liter and sometimes a variable amount of lactic and butyric acid is present. During the second stage, when the tubercles undergo softening the gastric juice is found normal or of diminished acidity. Finally, in the stage of cavity-formation, the secretion will be entirely insufficient and a chronic gastritis with mammilated mucous membrane and interstitial periglandular inflammation will supervene. Anorexia is present, digestion is accompanied by feelings of oppression and foul-smelling regurgitations and vomiting are common and preceded by nausea and pain. The stomach contents contain only a trace of free acid, pepsin is much diminished, and rennin entirely absent. Diarrhea often accompanies the gastritis and hastens the end. The initial hypersecretion is explained by the authors by an irritation of the vagi, the final hyposecretion by the cachexia.

Tuberculin Test in Consumption.—It is often impossible to detect by means of physical examination, if a patient is suffering from incipient tuberculosis or if a formerly active process has passed into the latent stage. For such cases, E. Fischer (Correspbl. f. Schw. Aerzte, Oct. 1, 1903) finds the tuberculin test invaluable. A patient may feel well and gain in weight and the physical signs may be insignificant, so that the physician is inclined to pronounce the case cured. Yet a rise of temperature may follow an injection of tuberculin which indicates that another course of hetol treatment is in place. A cure is thus established on an exact scientific basis and is no longer guesswork. In one apparently advanced case, no reaction followed, so that the patient, who was hitherto regarded as a hopeless consumptive, could be definitely cured of his lung abscess.

Stomach Contents in Various Diseases.—Votruba and Mixa (Bull. Gen. de Therap., Oct. 8, 1903) have systematically examined the stomach contents in a large number of diseases with the following results: In tuberculosis there is hyperchlorhydria and hyperpepsia at first, later hypochlorhydria with varying amounts of pepsin and rennin. Nephritis is generally marked by hypochlorhydria with normal amounts of pepsin and rennin. Hypochlorhydria also goes with osteomalacia. No constant figures were obtained in diabetes mellitus, chlorosis, neurasthenia, or hysteria. With cancer and ulcer of the stomach, the usual characteristics were found. No parallelism between acid, pepsin and rennin could be found in the various diseases studied. In hypochlorhydria, hydrochloric acid is indicated, but where there is an excess of acid, calcined magnesia has a much more lasting effect than bicarbonate of soda.

The Blood in Congenital Heart Disease.—An interesting and fairly constant symptom accompanying the cyanosis of congenital heart lesions is a marked increase in the number of red blood cells. In a series of cases observed by E. Fromherz (Münch. med. Woch., Oct. 6, 1903) figures as high as 9,800,000 were obtained. In one case where the autopsy subsequently revealed pulmonary stenosis and open foramen ovale, a peculiar attack was noticed several months before death. The patient suddenly became almost completely black in the face and suffered from extreme dyspepsia, while the heart action was heaving and the pulse strong and hardly increased in frequency. Probably a dilatation of the right auricle had taken place and most of the blood had passed directly into the left auricle and from there into the general circulation, instead of right ventricle and pulmonary circulation. The increase of red cells is to be looked upon as a compensating change. Since the amount of blood flowing through the lungs is less than normal each given amount of blood must present a larger oxygen-absorbing surface to meet the demands of the body. Despite this, cyanosis is common since the number of red cells in each cubic centimeter has its limits and can rarely exceed 8,872,500, if the cells are of normal size.

Serum Therapy of Scarlet Fever.—If it is taken for granted that all streptococci are closely related, it would seem that all antistreptococci sera ought to be able to exert a specific influence on scarlet fever cases. In a discussion of this question, H. Schiller (Medicine, Oct., 1903) points out that experiments have shown that sera which have been produced with virulent and unchanged streptococci agglutinate very promptly all the forms of streptococci, and this variety of sera should therefore produce the best results in treating scarlatina. Sera of this type are those of Moser and Tavel. The author reports two cases in which the prognosis was very bad. They were combined with sepsis and the usual measures including the use of unguentum Credé did not produce any improvement. Resort was then had to the ordinary antistrepticoccus serum sold in the open market. This is prepared after the manner of that of Marmorek, and was used because neither of the other types could be obtained. From 15 to 20 c.c. of the serum was injected in each case, on two occasions from three to five days apart. The improvement was almost immediate, the general condition improved, temperature fell, pulse grew stronger, and the glandular swellings became reduced. Relapses had occurred in each case before the second injection of serum, due probably to a renewed invasion of the system by streptococci originating in the glands. The reaction, however, was prompt.

What Drugs Can One Use Against Diabetes?—Kaufman in Gazz. degli osped., (Oct. 6, 1903) makes a systematic study of various methods of treatment of diabetes. In 11 observations, opium or its alkaloids were used, six times successfully, three times unsuccessfully, two with doubtful results. Bromides are useful where glycosuria is combined with neurasthenia. Bichloride of mercury diminished the sugar in many cases, but was without result in one-third of the patients. Carbolic acid was without effect in 11 cases of grave glycosuria; in five cases there were some results, in two cases the result was favorable. Salicylates had no harmful results, except in diminishing the appetite. Salol worked better. Antipyrene administered to seven diabetics had no effect except in disordering the gastro-intestinal tract. Piperazine increased the glycosuria in one case. Jumbul, in two cases, produced a distinct improvement, in three the effect was slight, and in two was absolutely negative. The author concludes that opium, salicylates and jumbul are the only drugs that modify glycosuria; he advises opium in severe cases with serious complications, and salicylates in milder cases or after a course of opium treatment.

Transmission of Tuberculosis.—During recent years it has been the general belief that tuberculosis is acquired usually by the inhalation of the tubercle bacilli into the respiratory tract. That this is a frequent method of infection must be acknowledged by all, but the fact that infected food is the means of communication in a large number of instances, even when the lesions of the disease appear first and principally in the respiratory tract, is being urged by a great many authorities. J. O. Cobb (N. Y. Med. Jour., Oct. 3, 1903) cites the experiments of Nicholas and Descas, who fed fasting dogs on tuberculous sputum and in several instances were able to detect tubercle bacilli in the thoracic duct three hours after such ingestion, even when no lesion could subsequently be detected in the intestinal tract.

Even in the intraperitoneal inoculation of guinea-pigs it is frequently noted that the lungs manifest extensive lesions when there has been very little involvement elsewhere. It is not unreasonable to suppose that the tubercle bacilli when free in the blood locate by preference in the lung tissue just as other germs which seem to have a predilection for particular tissues of the body. The probability is that cows almost always acquire the disease through their food, and it is a simple matter to understand how this is possible. They frequently lick the same lumps of salt and drink from the same troughs or even eat from the same bins. By coughing they probably infect the food or receptacles before them. The infection of swine by means of the gastro-intestinal tract as the usual manner is undisputed. It is more difficult to prove the mode of infection in man, but it is contended that the gastro-intestinal tract is a very frequent avenue of entrance. The food and water used by a family, in which there are one or more careless tuberculous patients, can be very easily contaminated. Flies undoubtedly serve as carriers of tubercle bacilli, for sputum is always especially attractive to them, and the presence of bacilli has often been demonstrated upon their proboscl.

Quincke's Disease.—This disease, first studied by Quincke in 1882, is an angioneurotic edema, according to Bastogi (Riv. critica di Clin. Med., No. 32), acute, idiopathic, but circumscribed, the swellings are from 2 to 10 cm. in diameter. It seldom affects the mucous membranes, is temporary, generally soft, elastic, white or red, indolent, accompanied by a sensation of tension. It returns frequently, with evident periodicity, and is sometimes hereditary. It usually involves the superficial layers of the skin, but sometimes invades the subcutaneous tissue. It attacks the extremities, the lids, the labia, and, less frequently, the trunk. It has even been seen in the retrobulbar cellular tissue causing exophthalmos. The symptoms vary according to the location of the edema. In cases of edema of the glottis or larynx it can become fatal. The most common cause, when it can be determined, is refrigeration or traumatism. Emotional shock, deficient nutrition also produce it. The cause is a local change in the minute blood vessels, and their vasomotor nerves causing a slowing of the circulation of the blood, from some local toxemia probably, capable of provoking acute saturation of the tissues with serum. An irritation of the vasodilators rather than a paralysis of the vasoconstrictors is probable. This irritation increases the serous secretion by the change in the blood and in the walls of the blood vessels. Some cases present a symmetrical involvement of different areas, suggesting a central origin. These cases are accompanied often by vomiting. Acute angioneurotic edema is to be distinguished from edemas of mechanical origin, from inflammatory, nephritic, or myxedematous origin; also from edema occurring in cases of hemiplegia, tabes and hysteria. The various cases of angioneurotic edema reported in literature have been associated with grip, articular rheumatism, gastro-intestinal disorder, uricacidemia, or gout. Other cases seem idiopathic, and not associated with any other diathesis or condition.

Syphilis and Suicide.—Four classes are mentioned (Alfred Fournier, La Presse Med., May 20, 1903): (1) Cases where the suicide is the result of a mental trouble arising directly from the syphilis; (2) cases where suicide is the result of despair of the patient, who has suffered from external syphilitic symptoms, which are of a serious nature, or so considered by him; (3) cases associated with the original announcement to the patient that he is syphilitic; (4) cases depending on the social situation where syphilis has definite relations with marriage, or social standing. The first group includes those cases, the most numerous of all, where a mental trouble is directly the result of the syphilis, that is to say, a syphilitic encephalitis, a gumma of the brain, a general paralysis of the insane, referable to the infection. In certain forms of syphilitic encephalitis suicide is a symptom, and at a very early period of the disease. It appears so suddenly that it overpowers the patient who has been in an absolutely quiet condition. It may appear after many years, or in cases of hereditary syphilis. In the second class, where shame of suffering a venereal disease or a disfiguring ulceration of the face, the writer advises all physicians to appreciate the special mental and moral attitude of his patients, so as not to be taken unaware by suicide from this cause. In the third case, where suicide follows the first notification of syphilis, the fault lies in an abrupt, tactless announcement on the part of the physician, to patients who are syphilophobiacs.

Excretion of Ammonia in the Urine.—The amount of ammonia excreted in the urine remains the same no matter whether much or little proteid is injected or if meat is allowed or not. A. Schittenhelm (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 5 and 6), however, finds that with a fatty diet, the amount of ammonia at once increases owing to an overloading of the organism with fatty acids and their decomposition products. Where there is no free hydrochloric acid in the stomach and the total acidity of the test-meal is low the amount of ammonia obtained from the urine is low also, and conversely, so that the gastric secretion seems to have a marked influence. In chronic degenerative disease of the liver there is also a general acidification, with greater excretion of ammonia. If now fat is given the figures obtained will be higher than in the normal organism.

Behavior of Leucocytes in Various Diseases.—The white cells were carefully counted in a number of diseases by P. Rekzeh (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 3 and 4), in the hope of finding constant relations of diagnostic value. The results were briefly: (1) In mercurial dermatitis, a slight increase of leucocytes by 1 or 2,000, the large lymphocytes and transitional forms occasionally increased, mononuclear elements normal, polynuclear leucocytes diminished and eosinophiles somewhat more abundant. These changes were all independent of the syphilis present. In excised pieces of altered skin eosinophiles were also abundant; they were more numerous in capillary blood, taking from the neighborhood of the eruption, than from venous blood. Their presence is accounted for by the irritation caused by the breaking down of epithelial cells. (2) Scarlet fever. Here an eosinophile increase independent of the general leucocytosis was present, which reached its acme when the eruption began to fade. The percentages varied between 1 and 12.5 in one series (children), between zero and 23 in another (adults); the average number was 8 per cent. at the height of the disease. (3) Measles was characterized by an absence of leucocytosis (4,200 to 4,800, with eosinophiles between zero and 5 per cent. in children and zero and 4 per cent. in adults. The greatest percentage was here also obtained during the fading of the eruption. (4) Erysipelas gives rise to a marked polynuclear leucocytosis with diminished lymphocytes, and complete absence of eosinophiles. (5) Diphtheria. A leucocytosis proportionate to the severity of the disease and due chiefly to increase of lymphocytes. In four cases myelocytes were found and in one a relative lymphocytosis was present four days before the onset of clinical symptoms. The eosinophiles were normal or diminished. (6) Leucemia. The eosinophiles varied here between 1 and 14.6 per cent., and were most abundant in the relatively benign and myelogenous types. (7) Pernicious Anemia. Here also an eosinophile leucocytosis is present only in the milder

cases, but high figures were never obtained (1 to 2.5 per cent.)

Diagnosis of Bone Metastases from the Blood.—The article of O. Kurpjuweit (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 5 and 6) forms an interesting contribution to blood-pathology. This author finds that if besides the indications of a severe anemia, a large number of myelocytes (4 to 17 per cent.) are present in the blood, even if the clinical picture is obscure, the diagnosis of malignant tumor with metastases in the bone may be made without hesitation. Myelocytes occur in the blood in small numbers (fractions of a per cent.) in diphtheria, pneumonia, and malignant tumors without metastases. They are found more abundantly in leucemia, but here poikilocytosis is absent, mast cells are increased and eosinophile cells are more common. Clinically leucemia and malignant secondary tumors in the bone may be very similar; in both there is advanced anemia, tenderness of the bones, hemorrhagic diathesis and an irregular fever. The absence of enlarged spleen and lymph-nodes will, however, speak against a leucemia. In pernicious anemia, myelocytes will never reach such high figures. The myelocytes in malignant tumors appear only when secondary nodes form in the marrow; they are a manifestation of disturbed hematopoietic function.

PHYSIOLOGY.

Contributions to the Physiology of the Kidneys and of Diuretics.—The diuretics are divided into three groups by W. v. Sobieranski (Pflüger's Archiv, Aug. 8, 1903). To the first belong caffeine and similar bodies, which principally lessen the resorptive powers of the contorted tubules and thereby bring about diuresis. In the second group are to be placed all the salts, which increase chiefly the filtration and osmotic properties in the glomeruli. The third class includes all those bodies, which in their effect, make them intermediate between the two other classes. These bodies are urea and kindred substances. In studying the histological effects of saline diuretics on the kidney, the author found a pronounced dilatation of masses of tortuous uriniferous tubules. Most characteristic was the appearance of a brush-like border in all those tubules of the above type with low epithelium. This is so typical that it undoubtedly is connected with the phenomenon of saline diuresis, and is to be regarded as a manifestation of the hygroscopic properties of the salts. The latter in the blood prepare the way for diuresis, which accordingly occurs in the glomeruli. As soon as the urine secreted in the Malpighian bodies reaches a certain concentration of salt, there occurs in the contorted tubules a shrinkage of epithelium, as the result of the hygroscopic action of the salt; hence the brush-like border of the epithelium. As soon as the saline concentration of the blood and urine sinks, the capacity of the epithelium to swell to its normal size has the upper hand. Thus, saline diuresis manifests itself in the kidneys by the play of two forces, the one determining the greater filtration of the urinary constituents in the glomerulus, the other consisting in the effect of concentrated saline solutions upon the uriniferous tubules. There results an osmotic struggle between the resorptive capacities of the epithelium of the contorted tubules and the hygroscopic properties of the salts. Caffeine hardly changes the form of the epithelium of the contorted tubules but increases their resorptive power. Urea lessens this power but exerts, when administered in large amounts, the same effect as salines.

The Digestibility of Vegetables.—An experimental contribution by A. P. Bryant and R. D. Milner (Am. Jour. Physiol., Oct. 1, 1903) indicates that so far as sources of protein or fat are concerned, the vegetables studied (potatoes, cabbage, apple sauce and green corn) may be considered as of little value. They do, however, contain carbohydrates, which the results of these and other experiments indicate to be quite well digested and absorbed; and they may, therefore, be considered as of value as sources of energy, a large proportion of which appears to be available to the body. The chief value of many vegetables, however, is perhaps aside from the nutrients or energy they furnish; they add a pleasing variety and palatability to the diet, supply organic acids and mineral salts, and give the food a bulkiness that seems to be of importance in its mechanical action in maintaining a healthy activity of the alimentary tract. Perhaps the result of these conditions is a favorable influence upon the digestion of other food eaten with the vegetable; at least such an effect was suggested by the results of some of the experiments.

Gastric and Intestinal Peristalsis.—A new experimental method of studying the peristaltic waves of stomach and intestines under different conditions, has been employed by F. Lommel (Münch. med. Woch., Sept. 22, 1903). Small dogs were fixed in the right lateral position and fed with milk or finely divided meat to which 15 per cent. bismuth subnitrate had been added and then Roentgen rays allowed to pass through the body from the right side below to the left side above. After two to six minutes distinct rhythmical waves began to appear at the large curvature. These rapidly became more distinct and extended to the pylorus, which became distinctly tube-shaped after nine to fifteen minutes. Ten distinct waves required about two minutes. The application of warmth did not increase the number or rapidity of the waves and likewise cold was of little influence. The addition of certain substances, such as somatose seemed to stimulate peristalsis. The influence of psychical conditions was very apparent. In restless animals or animals suffering pain during the experiment, no gastric movements were noticed for as long as two to three hours. Concerning the intestines, there is no question that antiperistaltic waves occur under normal conditions. Both stomach and intestines contract rhythmically and distinct periods of rest follow each larger wave.

The Differential Recognition of Human Blood from that of Other Animals.—Bordet has some time ago established the following fact: If the red blood corpuscles of a certain animal be introduced hypodermatically into the blood of another animal there will be formed in the serum of the latter substances possessing certain properties toward the blood of the first animal, known as agglutination, and hemolysis. This action is specific, inasmuch as the serum shows its effect only toward that animal and is inert as regards any other. The same is proved to be the case with other fluids of the body, such as milk. Several investigators went further in these experiments and established what is known as the biological method of differentiating the blood of man from that of other animals. P. N. Diatroptoff (Roussky Vrach, Sept. 13, 1903) resorted to this method in the rather notorious case of the murder of a boy said to have been committed for ritual purposes and which served as the immediate cause of the Kishineff massacre. The question to be decided (besides controverting the obstinate rumors fostered by certain people) was as to whether the blood found on the boy's clothing was human or not. To obtain the requisite serum, blood serum from man was injected into a rabbit. The human blood was collected from the mother's end of a cut placental cord into a sterilized tube, and then subjected to centrifugal action. During a period of twelve to sixteen days each rabbit received between 60 and 80 c.cm. of human serum. Six

days after the last injection the blood obtained from an experimented rabbit was compared with the blood of a healthy rabbit. Two drops of human blood in 5 c.cm. of a physiological salt solution when mixed with ¼ c.cm. of the serum from the experimental animals caused in one-half hour marked turbidity, and later on a sediment; while a mixture under the same conditions of horse's blood, or of human blood with that of another rabbit failed to give any reaction. The examinations of the dried blood on the boy's clothing took place four months after the presumed murder, and gave undoubtedly positive results. The author considers this biological method of blood examination of immense importance in legal medicine. The reaction is very evident and remains so for a considerable time, for almost two days.

Qualitative Difference of Spinal Reflex Corresponding with Qualitative Difference of Cutaneous Stimulus.—Qualitative differences between spinal reflexes provoked from the skin, according to C. S. SHERRINGTON (Jour. of Physiol., Aug. 24, 1903), are usually distinguished only in so far as dependent on differences in the regional locus of their initiation. But the variety of species of sensation elicitable from the skin suggests that possibly different reflex motor reactions attached to the different species of end-organs undoubtedly coexisting in one and the same skin field. The author found in experiments on dogs that this is really the case, the different kinds of nerve-endings situated in a certain cutaneous area possessing reflex spinal connections differing wholly inter se. For discrimination between certain sets of end-organs in the skin there are, in fact, available not only psychological criteria involving processes of sense, but data purely physiological with characteristics given in tensions of the musculature.

The Formation of Uric Acid in Birds.—The literature on the subject of the origin of urea in mammals and uric acid in birds is richly increased by the contribution of T. H. MILROY (Jour. of Physiol., Aug. 24, 1903). He found that such a mineral acid as hydrochloric acid in doses smaller than those which result in acid-poisoning, affect the uric acid synthesis, diminishing the transformation of ammonium salts into uric acid. The same occurs with lactic acid but on neutralization the effect is no longer produced. Galvanic stimulation of the liver aids the synthesis, while the presence of the electrodes alone inhibits it. When galvanic stimulation of the liver is employed in the case of birds under the influence of acid, the action of the former prevents the latter making itself felt. Although the excretion of uric acid is raised by giving nucleic acid, it is not certain that this is due to a direct origin from the purin radicle. The results which were obtained on giving hypoxanthin and caffeine, unlike those described by v. Mach, also tend to show that the direct transformation of purin bases into uric acid is not an important mode of origin in the bird.

The Proteolytic Activities of the Pancreatic Juice.—The just criticism is made by W. M. BAYLISS and E. H. STARLING (Jour. of Physiol., Aug. 24, 1903) that although one of the earliest of the modern researches on the pancreatic juice, namely, that of Corvisart, was made on the pancreatic juice itself, as secreted into the duodenum, nearly the whole of the modern ideas on this subject are based on experiments carried out, not on the juice, but on extracts made in various ways from the gland itself. The authors find that under no circumstances does the pancreatic juice, as secreted, contain trypsin. Fresh pancreatic juice contains trypsinogen, and a weak proteolytic ferment resembling somewhat erepsin. This latter will digest fresh fibrin, or caseinogen, but has no influence on coagulated proteid or on gelatin. Trypsinogen is a stable body, only slowly altered by standing in alkaline or acid solutions. It is converted into trypsin by enterokinase. No other substance can effect this conversion. Trypsin is not an expression for two bodies, enterokinase and trypsinogen acting together, but is a third substance produced as a result of the interaction of these two bodies, *i.e.*, enterokinase acts on trypsinogen like a ferment (Pawlow) and converts it into trypsin. This substance is extremely unstable, and is rapidly destroyed, especially in alkaline media, and at the body temperature. This autodestruction is greatly retarded by the presence of dissolved proteids or peptones. Enterokinase is a product of the secretion of the small intestine, and mainly of its upper end, but of no other parts of the body. It is not found in blood fibrin, lymphatic glands, or leucocytes. The smallest trace of enterokinase will convert a large quantity of trypsinogen into trypsin if sufficient time be allowed. It is stable in watery solutions at 15° C., but is rapidly destroyed at 40° C.

Observations on Precipitins.—Rabbits were treated with injections of the separated proteids of oxserum by A. HUNTER (Proc. Physiol. Soc., Jour. Physiol., Aug. 24, 1903), and precipitins were obtained in every case, but the most striking fact noted was that any injection performed on a rabbit whose serum was already rich in precipitin, led to an immediate diminution, and indeed usually to a complete disappearance of the precipitating substance from the blood. It was only gradually reproduced, reappearing about the second or third day, and attaining its maximum amount about the fifth or sixth day. Each successive maximum was of course higher than the previous one. The leucocytes followed a course exactly inverse to that of the precipitins.

The Effect of Prolonged Putrefaction on the Nuclein Bases of Feces.—The results of a series of experiments performed by A. SCHITTENHELM (Hoppe-Seyler's Zeitsch., July 31, 1903) show that prolonged putrefaction causes the disappearance of the nucleins from the feces, with the exception of a small residue. Undoubtedly this disappearance is to be attributed to the decomposition effects of bacteria, either alone or with the aid of ferments.

The Effect of Enhydrina Poisoning.—One of the commonest of the very poisonous *Hydrophidæ* or seasnakes is the *Enhydrina Bengalensis* according to L. ROGERS (Proc. Physiol. Soc., Jour Physiol., Aug. 24, 1903), its venom being 10 times as powerful as that of the cobra. It produces complete paralysis of the phrenics and partial paralysis of the sciatics, and causes the blood to become very dark in color and to clot firmly and quickly when removed from the body. There is a typical paralysis of the respiratory centers and motor end plates, the latter being most marked in those of the phrenic nerves, this resembling that produced by cobra poison.

The Products of the Proteolytic Action of an Enzyme Contained in the Cells of the Kidney.—The following substances have been identified by H. D. DAKIN (Jour. of Physiol., Aug. 24, 1903) as products of the action of the kidney enzyme, recently discovered by Hedin and Rowland; the enzyme acting in acid solution: ammonia, alanin, and ammioisovaleric acid, leucin, pyreolinie carboxylic acid, phenylalanin, tyrosin, lysin, histidin, cystin, hypoxanthin, nidol derivatives which in some cases gave the reactions of skatol-amido-acetic acid, together with an insoluble residue of paranuclein. In the main the products of the intracellular enzyme are identical with these of the ordinary extracellular tryptic digestion of proteids, although arginin and aspartic acid were not formed in appreciable quantity.

The Influence of Carbohydrates Upon the Putrefaction of Proteids.—A theoretical and experimental

study of this question is offered by S. Simnitzki (Hoppe-Seyler's Zeitsch., July 31, 1903). Considered from the theoretical standpoint, he believes it is probable, in opposition to the theory of Pasteur, that animal life is possible without the presence of bacteria in the intestine. This was established experimentally by Thierfelder and Nuttal. On the other hand, the researches of Schottelins on hens showed that whereas life is possible without intestinal bacteria, yet the development of the organism is not a normal one and there is a diminution in the energy of the vital manifestations, when the contents of the intestine are sterile. The advances in the knowledge of intestinal auto-intoxication led to a search for remedies, and following on the one hand the suggestion of Bouchard with regard to intestinal disinfection, various pharmaceutical agents were tested, and on the other hand the result of empiricism, the influence of various dietetic measures was tested. The investigations of Biernacki and Eisenstadt showed that the carbohydrates have only a slightly inhibitory action upon intestinal putrefaction. With regard to a milk diet, many authors are unanimous that this leads to a marked diminution in intestinal decomposition. These authors do not agree, however, as to what constituent or constituents of the milk are responsible for this effect. The following suggestions have been made, namely: (1) casein, unlike the other proteids, is less apt to undergo putrefaction; (2) milk sugar prevents putrefaction; and (3) this process is prevented by lactic acid and other decomposition products of milk. Experiments on the treatment of wounds performed during the brilliant age of antisepsis, have shown that concentrated sugar solutions are capable of influencing the vitality of bacteria, and this was practically applied in the cleansing of wound-surfaces. In 1888, J. Bey suggested the use of ordinary sugar-syrup in the treatment of burns. The progress of bacteriology has rendered it possible to teach that suger, even in very weak concentrations, has at times an unfavorable influence upon the vital manifestations of certain bacteria, for example, the *Staphylococcus pyogenes aureus*. It naturally appeared to be of some interest to determine the fate with respect to intestinal antisepsis, of sugar administered per os. The experiments of the author showed the following: The decomposition processes of sugar and proteid begin in putrefying mixtures at the same time, but do not proceed proportionately. The presence of sugar inhibits the decomposition of proteid by bacteria, and the quantity of decomposed albumin stands in reciprocal relationship to the content of sugar in putrefying mixtures. The various forms of sugar have a different effect; the inhibitory effect of milk-sugar (50 per cent. solution) is greater than that of similar solutions of grape-sugar and galactose, while the effect of grape-sugar is greater than that of galactose. The acids formed from sugars taken in by the mouth, have a similar effect: lactic acid, as well as it salts, has an important action in the prevention of the decomposition of proteids.

The Composition of the Blood-proteids in a Case of Alcaptonuria.—This is an hereditary disease characterized by the presence of homogentisinic acid in the urine. Tyrosine and phenylalanin have been recognized as the mother-substances of homogentisinic acid. E. Abderhalden and W. Falta (Hoppe-Seyler's Zeitsch., July 31, 1903) found in a case of alcaptonuria, the presence of homogentisinic acid in the blood, and that the proteids of the blood in this case contained tyrosin and phenylalanin and in the same proportion and amount as these are present in the blood of normal individuals. This proved that the disturbance underlying alcaptonuria is to be sought neither in the intestinal canal nor in the process of absorption. It depends upon the quite localized, specific disturbance in the catabolism of proteid. This has been found also to be the case in the cystindiathesis.

NEUROLOGY AND PSYCHIATRY.

Bladder Center in the Cortex.—The fact that children obtain full control over the bladder only as their intellectual faculties develop, makes it probable that a cortical center controls the innervation, besides the lower centers in the cord and sympathetic ganglia. Almost conclusive proof is offered by a case of M. Friedmann (Münch. med. Woch., Sept. 15, 1903). A boy sustained a fracture of the vertex of the skull without any focal symptoms, except that there was at first a difficulty in urination and later, incontinence, which persisted for over a year. The site of injury corresponded to the upper third of the posterior central convolution, directly behind the arm center. Why the other hemisphere did not assume vicarious function could not be explained.

Brain Surgery in Epilepsy and Idiocy.—Great hopes have been held out from time to time by surgeons who have operated upon cases of epilepsy and obtained what appeared to be temporarily, at least, very favorable results. A careful investigation of these cases later, however, almost always tends to reduce the ardor of enthusiasm for surgical interference. Cases for operation must first of all be carefully selected for there is only a small percentage of epileptics upon whom an operation is justifiable. The epilepsies which affect the motor side of the body promise most for surgical treatment. When the attacks are psychical, or silent in form, causing no commotion in the muscular system and no change in posture, surgery can be of little avail. Operations should be confined to cases in which the attacks are of *grand mal* or Jacksonian type, and will seldom be found of value in the *petit mal* or psychic type. W. P. Spratling (N. Y. Med. Jour., Sept. 12 and 19, 1903) reports 33 cases of epilepsy operated upon, most of them being carefully selected and offering the best chances of benefit. In 21 there was no improvement either temporary or permanent. In 8 the attacks were lessened in frequency and severity, the operation being a part of the treatment only. In 3 the disease was much worse after the operation. In one, in which there was apparent recovery, the operation was done for the removal of the uterus and appendages, which were seriously diseased and which evidently periodically produced a form of auto-intoxication. In only four was there any decided improvement and it was impossible to say how much benefit was derived in these cases from the medical treatment which was also maintained. Certainly these results are not very hopeful. It should be said, however, that there was no death from operation. In regard to idiocy the results from operation are even less bright. There are, of course, many cases of idiocy in which it would be the height of folly to attempt any operation. Some cases of hydrocephalus, microcephalus or premature ossification of the fontanelles and sutures would appear, theoretically, at least, to offer some hope of relief. A report of 83 cases, which had been followed for some time after operation, showed that 20 died from the operation itself or soon afterward; 54 were unimproved, and only 9 were benefited. The 9 who were improved showed it mostly in being quieter. This must not be taken for a gain in mental power for it frequently means the opposite. Jacobi says: "It appears in the face of so many deaths and so few results, that the operation is not promising to mankind. The operations thus far performed do not effect what they were intended for; they do not even enlarge the cavity."

THERAPEUTICS.

Bromide of Methyl Atropine.—A further experience with atropine in the treatment of asthma has led G. CAMPANELLA (Gazz. Osped., Sept. 20, 1903) to give the preference to the bromide of methyl atropine; this preparation being, in his experience, devoid of the untoward effects of atropine sulphate, and in many instances relieving the dyspnea within a few minutes, when injected in the proportion of from a half to three quarters of a Pravatz syringeful. Though conferring almost immediate relief of the respiratory distress, the remedy induces dryness of the throat and, in some patients mydriasis with elouded vision, and ischuria.

Treatment of Anthrax with Oxygen.—The various methods of treating anthrax are reviewed by G. BARNICH (Jour. Méd. de Bruxelles, Sept. 24, 1903) who has had his best results from local application of a current of oxygen gas. This is accomplished, when the pustule has broken down, by directing, upon all parts of its surface, a current of oxygen from a cylinder containing the gas under a pressure of twenty atmospheres. This treatment is continued for fifteen minutes and is supplemented by injections of the gas into the surrounding tissues by means of a Pravatz needle attached to the end of the delivery tube, and compresses saturated with dilute peroxide of hydrogen. If the anthrax be seen in the stage of tumefaction before suppuration has set in, injections of the gas into the tumefied tissue and surrounding inflammatory areola, followed by a dressing saturated with peroxide frequently suffice to abort the pustule. The Pravatz needle should be inserted at numerous points, and at each introduction the gas should be allowed to flow for about a half minute or until gaseous crepitation is felt; the tumor being thus isolated, as it were, in an atmosphere of oxygen. From one to two treatments usually suffice to effect a eure.

Spurious Creosote.—The secretary of the New York Board of Pharmacy, C. S. ERB (Merck's Report, Oct., 1903) finds on personal investigation that a number of New York druggists dispense "coal-tar creosote" when "creosote" is preseribed. The creosote of the U. S. Pharmacopœia is wood creosote, preferably that made from beechwood, while coal-tar creosote is a distinctly different substance and poisonous. The Board intends to proceed vigorously against these pharmacists for their criminal negligence.

Atropine in Intestinal Occlusion.—In the ease reported by VOLTMAN (Roussky Vrach, Sept. 13, 1903) there was a sudden access of pain in the left lower abdominal region; this was followed by obstinate constipation and vomiting of green matter. Castor oil failed to move the bowels. The general condition not bad, pulse 92, temperature raised but slightly. Palpation causes pain; abdomen rigid to touch. Treatment—at first expectant—consisted of the administration of opium and pieces of ice internally. An enema on the sixth day produced no effect, except in the way of intensifying the pain to a very marked extent. A hypodermic injection of atropine, 1-40 of a grain, was then administered, followed in an hour by another of 1-30 gr., and in two hours by 1-20 gr. Pains better after the second, and entirely disappeared after the third injection, and the vomiting ceased; the bowels moved in a few hours; patient discharged convalescent on the next day. In the second case, that of a woman aged forty years, the symptoms of ocelusion were signalized by severe pains, inflated abdomen, general malaise, constipation of ten days' duration, vomiting of green stuff, normal temperature, and pulse of 105; face characteristic; hiccough and belching. A hypodermic injection of 1-30 gr. of atropine eased the pain somewhat, but had no influence over any of the other symptoms; two injections of 1-20 gr. each failed of any result; meanwhile the general condition of the patient, as could be judged by the failing pulse, grew gradually worse, and a laparotomy was resorted to. The peritoneum contained a serous flaky fluid, the intestines were at certain spots markedly injected; at one spot there was considerable strangulation of the intestine which was freed without great difficulty. The condition of the patient became so alarming that the operation had to be discontinued, and patient died in one-half hour from cardiac paralysis. The reader is left to draw his deductions from the above cases as to the utility of atropine in intestinal occlusion.

Large Doses of Unguentum Hydrargyri.—Some seven or eight years ago Dr. Ivanoff recommended warmly large doses of mercurial ointment in post partum parametritis, and M. BIELOGLAZOFF (Prakt. Vrach, Sept 20, 1903) reports a few cases in which he obtained very favorable results from the drug. Of the cases reported we note one in which there was a parametritis after delivery; this was treated principally with vaginal balls of ten grains of mercurial ointment each and hot injections. As no results were obtained inunctions of two and three drams of the ointment were resorted to, increasing the dose to an ounce; as a result the exudate disappeared in a few days, and the patient left the hospital entirely recovered. During fifteen days of treatment 60.0 grm. of the ointment was used up. In another case the amount used up reached 75.0 grm. Among the conclusions we note as particularly interesting the one where the author ascribes to mercury the diminution of pain, and the absorption of the exudate. There were no mercurial after-symptoms of any kind observed in any of the patients. The whole matter is, however, as yet sub judice.

Lysoform.—Lysoform really seems to have properties which make it far superior to other disinfectants, according to B. GALLI-VALERIO (Therap. Monatsh., Sept., 1903). Nickeled instruments, even if kept for months in a three-per-cent. solution are not attacked. Used for the hands in 3- to 10-per-cent. solution, it deodorizes and renders the skin smooth. A 1- to 2-per-cent. solution is serviceable as mouthwash. Animal experiments show no or only slight toxic action. Feces and urine mixed with small quantities of the drug were still odorless after three months. Colon bacilli did not grow, even in weak dilution, and experimental peritonitis in guinea-pigs could be cured by intraperitoneal injections of a 2-per-cent. solution.

Glycosal in Rheumatism.—The properties of glycosal are praised by H. RATZ (Therap. Monatsh., Sept., 1903), since this drug, by virtue of its peculiar chemical composition, passes the stomach unchanged and liberates salicylic acid in the intestines, so that all gastric irritation is avoided. General and local symptoms disappear more readily than with aspirine but endocarditis cannot be prevented any more than with other salicylic acid compounds. After-symptoms were not observed except a slight pruritus and tinnitis aurium. Glycosal is also absorbed from the unbroken skin if alcohol, turpentine or some other volatile substance is added to the ointment.

Treatment of Dysentery.—A rapid, almost specific action is exerted upon pathological conditions of the intestines, such as are common in the tropics by a decoction of cortex granati, simarubæ and lignum campeche with the addition of some silver nitrate. L. KÖHLER (Therap. Monatsh., Sept., 1903) was able to cure almost hopeless cases with a tablespoonful of this mixture every twelve hours. The most delicate infants and patients with weak digestive organs experienced no nausea or untoward symptoms and amelioration already occurred in twelve hours.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, NOVEMBER 21, 1903.

THE KAISER'S CASE.

WE have waited for more definite details as to the case of the Emperor of Germany before commenting upon it. The end of last week proved the advisability of such delay, since it brought the authentic report that while the growth in the Emperor's throat was spoken of originally as a polypus this was only a generic name loosely applied. It was not a true polypus in the sense of being properly pedunculated or having a true stem but was on the contrary of sessile character and its presence had brought considerable inflammation all over the vocal cord on which the polypus was situated.

This presents quite a different phase of the case from that which was apparently to be gathered from the original newspaper reports. Needless to say, a sessile polypoid tumor, with apparently a distinct tendency to infiltrate neighboring tissues, is much more dangerous as regards possible future malignant contingencies than would be a thoroughly pedunculated neoplasm affecting cells extraneous to itself only because of the irritation of its presence and the pressure of its growing tissue constituents.

The case has, of course, attracted widespread attention and has renewed the discussion of the subject whether cancer is hereditary or not. The Kaiser's father and mother both died of cancer and this would seem to add distinctly to the risk of any tumorous formation in his case proving eventually malignant. The whole question turns on the significance of heredity in such cases. There is no doubt that cancer seems to run in certain families and that in something over one-third of the cases that come under observation a family history of cancer in the more or less immediate ancestry can be traced, if the inquiry is only made with sufficient assiduity. There are those, however, who insist that notwithstanding this apparent etiological influence of heredity the question of inheritance is entirely due to coincidence rather than to any pathological tendency in the tissues.

At the present time, notwithstanding all the investigation of the etiology of cancer that has been undertaken in recent years, there is no generally accepted theory of causation. Prominent pathologists, who have made a specialty of the etiology of cancer, are prone at the present moment rather to accept one of the old theories of etiology in malignant disease than to concede that the affection is due, as many bacteriologists claim, to the presence of a parasite in the tissues. The most popular theory of cancer etiology remains that of the development of certain misplaced portions of tissue which were faultily included amid tissues more or less foreign to them during the process of embryonal development. Any injury in the neighborhood of these misplaced bits of tissue or any chronic irritation that weakens the resisting powers of neighboring cells may lead to the development of the cancer nodule to such a degree as to cause the death of the person in whom these embryonal tissue inclusions had been slumbering for many years.

It is easy to understand that this theory favors the influence of heredity as a factor in the causation of cancer. It is well known that tissue defects of various kinds run in families. Small tabs of tissue near the ears, for instance, are a characteristic family trait in many persons and may be traced for many generations. Other family birthmarks of many kinds, but all of them due to redundancies of tissues, are so common as no longer to attract much attention. They are considered to be family traits and no further thought is given them by the observer. They are really the best possible evidence for the inheritance of such tissue anomalies as might give rise to cancer and for cancerous family heredity.

The attack in the case of Emperor William is by no means encouraging, as the bulletins of his specialist attendants seem to indicate. Prof. Orth's pathological findings with regard to the material removed fail utterly to have weight in the case when we recall that on three different occasions the late Prof. Virchow examined portions of the tumor from Kaiser Frederick's larynx, yet failed to find any evidence of malignancy at a time when the clinical diagnosis of malignant disease was already settled in the minds of the German medical attendants.

The whole case is only another lesson in our lack of definite knowledge with regard to cancer and the consequent necessity for the greatest care in the prognosis of these borderland affections which, in tissues liable to frequent irritation in the exercise of normal functions, as is surely the case in Emperor William's larynx, may well take on malignancy in spite of every precaution in the treatment of an originally benign neoplastic process.

THE PRACTICAL ELIMINATION OF YELLOW FEVER.

It has, it seems, been long a mooted proposition among scientific observers, particularly with those who labor in the fields of the Spanish possessions, as to which class of the Latin colonial races can be regarded anthropologically, as the "fittest." This vexed question now appers to have been definitely answered by the inhabitants of Protera, in Mexico, who have, it is reported, decreed that the only survivors shall be those who are untainted by yellow fever The alcalde and council have sustained their action, and orders have been issued that all sufferers of the disease shall be promptly poisoned as soon as the symptoms can be identified or the diagnosis be made beyond a reasonable doubt.

As is now well known, a serious yellow fever epidemic has been raging along the Rio Grande for some weeks past, and the cases have run up into the thousands, while the death rate, as could only be expected among such unhygienic surroundings, has been appalling. In the face of such a condition of affairs it became apparent—even to the Mexican mind, which, like the Mexican cayuse, seldom stands without hitching—that "something must be done." They were perfectly willing to admit that the mosquito carried the germs of the infection, and thus spread the epidemic, but they were naturally much more interested in the "stamping out" of the disease itself than they were in the theory of its etiology. Gauze nets did not a prison make, at Laredo, nor mosquito bars a cage at Monterey. Dr. Stiles had not succeeded in breeding his *Stegomyia fasciata* destroying parasites, as duly scheduled in the daily newspapers, with a photographic attachment, and it was more than evident to the *Ayuntamiento*, or "selectmen" of this Mexican township that if any result was to be attained some other means certainly must be employed.

That this method of suppressing the ravages and spread of the disease is somewhat drastic is true, but can it be denied that it would be thorough? Is there any logical doubt but that it would prove effectual? Thus we know that the mosquito is the principal, if not, as claimed, the only vehicle, for the transmission of the disease, for we have been taught that if an insect of the proper species bites a patient suffering from the malady and subsequently stings a perfectly healthy individual, that he will, in turn, be inoculated, and that the fever will thus spread and be carried from person to person and from town to town.

It is proverbially a poor rule that will not work both ways, and all equations have two sides. If the mountain could not be brought to Mahomet, and if the mosquito vehicle could not be eliminated, why not take the founder of Islam to the hillside and kill the patient as soon as the symptoms are developed, and thus destroy the focus of infection? Dead and buried, they could not furnish food for the net-evading mosquitoes, and the epidemic would terminate, from the want of fresh inoculating centers. Men have died and worms have eaten them, but there are no reported cases of the ubiquitous mosquito having penetrated six feet of earth.

As to the City Fathers of Protera, to them we make our bow. The blue ribbon of originality should mingle with their civic ermine, and their reasoning is sound, even if hardly practicable in other communities that cannot boast of such an ancient civilization. We must remember, too, in their defense, that even if their promulgations strike us as a little arbitrary, that they are surrounded by their friends and immediate relations, and that they are doubtless actuated, in a Spanish way, by the belief that they are not only doing the greatest good to the greatest number, but that from previous experience they have every reason to believe that the poison which they are to administer is no quicker in ac-

tion, or more certain in results, than the fever that they are fighting.

We must, however, admit that they are doubtless tinged with a certain local coloring, and are imbued with an exaggerated idea of the value of the lives that they are seeking to preserve. For the ordinary American cowboy, who has been brought in contact with the lower Mexican classes, seems possessed of a fixed and firm belief, which he is prepared to argue, even at the pistol's point, that the intrinsic worth of a dead "Greaser" is as a hundred to one of the live article; and that a race, whose sole virtue—early rising—is simply the fruit of a desire to have more time in which to loaf, can hardly spend its leisure better than in the convalescence of a tedious and lingering disease.

But, be this as it may, the scheme strikes us as not only novel, but efficacious, and as it originated in Mexico, we should advise that the experiment be made there during the present epidemic, as they suggest—that the drugs employed should be imported, and that they should be administered on a holiday, to avoid delay, and to prevent such a meritorious plan from being forever lost in the national *mañana* of the country.

EXPERIMENTAL BIOLOGY AND MEDICINE.

Few medical societies are able to present a set of proceedings containing so much interesting and suggestive material as is to be obtained in the brief account of the last meeting of the New York Society for Experimental Biology and Medicine, which will be found on page 957 of the last issue of the Medical News (Nov. 14). There is just that combination of the original in biological science with possibilities of direct medical application that is sure to make valuable working material when the principles experimentally discovered are tested by actual practice. Dr. Park's article on the occasional presence in the blood of untreated adult animals of large amounts of substances agglutinating many bacteria gives an excellent idea of how much wider than is ordinarily supposed is the problem of agglutination and its significance. Agglutination is probably connected with immunity and the subject of natural immunity is one of the most interesting in the whole domain of medicine. Just why some people contract certain diseases while others apparently of similar constitution and without any known artificial protection remain refractory is one of the mysteries that modern pathologists are more interested in solving than almost any other of the obscure problems which come up for their consideration. It is very clear that this natural agglutination described by Dr. Park is going to be the source of many errors and a number of false hopes unless the greatest care is exercised in precautions against possible error before definite announcements of results are made. It would seem that even such excellent authorities as Shiga, the discoverer of the bacillus of dysentery, and our own Flexner were led into error because of this hitherto unconsidered factor in the problems they were working out. Duval and Bassett, who announced that they had found the dysentery bacillus in a number of cases of cholera infantum a little over a year ago, were certainly misled to false conclusions, and their mistake is due to the assumed principle that the existence of agglutinating powers in the blood serum of certain patients was the proof of the fact that they were being affected by certain forms of bacteria. It is interesting to find that young animals have very few agglutinins in their blood, and that therefore probably the same thing will hold true for young children. It is possible that the first agglutinating powers obtained by the child's blood are derived from its mother's milk, and are possibly due to the fact that this fluid has been influenced by the immunity to certain diseases produced by attacks of these specific diseases during the mother's previous life.

Dr. Calkins' discussion of the smallpox organism seems to demonstrate that the appearances observed in smallpox cases are those of a protozoan parasite, since the different stages of the organism have been definitely recognized by him. A very interesting side-light on smallpox is thrown by the demonstration of a corresponding parasite in certain forms of *Paramœcium*. This is a very common lower organism which exists in abundance in pools and swamps, and may even be found under certain circumstances in ordinary drinking water, and it is not impossible that it may prove to be the host of the smallpox organism outside of the human body. Now that the secondary hosts for malaria and yellow fever have been demonstrated, it may be expected that further such important steps in biology will be made with quite as beneficial effects in practical medicine. If this special bit of progress should come for smallpox next it would indeed be an important advance for sanitary science and prove of the greatest possible benefit to the race.

Dr. Meltzer's demonstration of the effect of ligature upon the circulation in sciatic nerves is an eminently practical demonstration of the influence of the peripheral circulation on the nervous system. When a single ligature is applied to the sciatic nerve and methylene blue is injected intravenously into the animal, the nerve becomes completely stained, just as if there were no ligature. When two ligatures are applied, however, some distance apart then the portion between the ligatures does not become stained blue, though the peripheral portion of the nerve beyond the external ligature and the proximal portion inside of the internal ligature do become colored. It is evident, then, that a considerable part of the circulation of nerves is derived from the periphery of the body. No matter how distant from one another ligatures are applied along the trunk of a nerve like the sciatic, no staining is found between the ligatures. Therefore, when any pathological condition causes a lessening of the circulation in the skin and outlying portions of the body, nervous nutrition must suffer. This explains why hydrotherapy, massage, gentle friction of any kind, and even the application of mild counterirritants is effective in producing distinct changes for the better in the peripheral nervous system.

We have selected for comment only certain of the articles under discussion before the Society, because they seemed of specially suggestive value. The whole proceedings, however, will be found of great interest. There is no doubt that this class of work and the combined investigations of biologists, experimental and medical observers will do much to bring up the standard of medical originality here in America and will also serve to redeem much of our medical society proceedings from the aspersions sometimes cast upon them of seldom containing original material of any value and of usually consisting of scarcely more than a farrago of things already long known and sometimes even long since unlearned.

THE CANCER PROBLEM.

The etiology and cure of cancer has occupied the minds of men and stimulated the research from the very dawn of medicine and to-day there is hardly a large laboratory, here or abroad, where diligent study is not directed to this most difficult of problems. It is to be regretted that with so enormous a literature—Behla has collected several thousand references up to 1901—such a discordance of opinions should still exist among the foremost pathologists.

Nevertheless much has been done to cure cancer. Operations have been so perfected—we refer only to the Wertheim method of hysterectomy—that many a patient remains free from recurrence for the rest of his life. With better education of the laity and keener diagnosis on the part of the physician, the disease is recognized earlier and hence the outlook in general is more favorable. Superficial cancers have even been cured without the knife, by such agencies as liquid air and arsenic, and, more recently, with Roentgen and radium rays. But the fact still remains that most internal cancers are hopeless and that the surgeon often operates only with the hope at best, of prolonging life for a few months.

In glancing over the more recent literature, one receives the impression that the parasitic theory of cancer is on the wane. The laity is somewhat late to discover what physicians have already discarded, hence it does not seem strange that the city council of Vienna recently recommended an exhaustive trial of cancroin in the hospitals. It will be remembered that cancroin was obtained directly from the cancer cells by Adamkiewicz, whose methods of bringing his discovery before the public were neither ethical nor convincing. Yet the idea does not seem altogether phantastical that in cancer the epithelial cell no longer works in unison with the other cells for the benefit of the entire body but solely for its own good, thus assuming the rôle of a parasite which when injected in attenuated doses may inhibit the growth of similarly abnormal cells in the body.

This theory has, however, met the same fate as the brilliant work of v. Leyden, the diligent research of Plimmer, Sanfelice and our own Gaylord, and the painstaking studies of Feinberg, who has devoted an entire volume to the finer structures of the protozoa and has demonstrated their close resemblance to the cell-inclusions of cancer. For every convincing article, a second one appears which points out some flaw in the observations. Recently T. Honda (*Virchow's Archiv*, Vol. 174, No. 1) has found the inclusions not only in glandular carcinomata but also in a number of other tumors and inflammatory processes, so that they can hardly be looked upon as specific.

Doubtless the real cause of cancer is not always the same. In certain organs, as in the uterus, the various transition stages between chronic inflammation, benign adenoma and malignant carcinoma are often so apparent, that the whole seems to

form one continuous process. It seems very probable that malignancy here is merely the end result of chronic irritation and inflammation. But there still remains a large number of cases in which the connection is not so clear and with a better knowledge of the life history of protozoa and with means to grow them outside of the body the mysterious hyaline bodies may still play a prominent part in pathology. Let us hope, then, that a satisfactory therapy may be not so far off.

ECHOES AND NEWS.

NEW YORK.

Trustees of Hospital Association Meet.—A meeting of the Board of Trustees of the Hospital Saturday and Sunday Association was held last week at the United Charities building. The application of St. Andrew's Convalescent Hospital for admission to the Association received favorable action. This brings the membership up to forty. The New York Hospital formally waived its privilege to receive a share of the annual collection. The general agent reported on the prospects of the coming collection, and ways and means for promoting it were discussed. The last collection resulted in a total of $83,500, a considerable increase over any previous year. The necessity for promoting a greater public interest in hospital support to meet the ever-increasing demand for free work was urgently presented by the representatives of various institutions.

Meeting of Hospital Guild.—The Hospital Guild of New York Hospital for Women held last evening its first meeting of the season. Reports were received from the committees which had continued work during the summer. Several physicians spoke of the standard of excellence preserved at the institution in One Hundred and First street. The hospital, however, has become overcrowded, and the Guild has decided to devote most of its energy this winter to raising a fund to start a new ward for children exclusively.

Bellevue's New Dispensary.—The old building formerly used as the Bellevue Medical College was thrown open this week, and will be known hereafter as the Dispensary for the Outdoor Patients. The structure has been renovated and made fireproof at a cost of $53,000. The first floor of the present dispensary building will be used for the dispensary proper and the bookkeeping department, while the remaining three floors are to be used as sleeping apartments for the female employes of the hospital, who heretofore have been forced to sleep in the basement of the hospital buildings.

Choice of Hospital Site Delayed.—There seems to be another hitch over the selection of the "site for a State hospital for the insane at some place in the counties in the northeastern part of the State, north of the County of Rensselaer." As Washington County is the only county between Rensselaer County and the boundary line of Vermont State, sites in no other county have been considered. The act providing for the selection of the site and the expenditure of $50,000 for land and necessary expenses of the commission, in preparing plans by the State architect, for expert engineers, etc., makes this condition: "Such site shall be so located as to be easily approached by railroad and other means of communication." Originally the committee of the State Lunacy Commission considered nine sites. The number has finally been sifted down to four, known as the Greenwich, the Cambridge, the Whitehall, and the Comstocks. Each contains the requisite 1,000 acres, and the committee says any one meets all the requirements. The members of the committee assert that the lucky site will win out on its merits, but there are others who believe that the much-agitated Republican politics of Washington will figure in the selection. In order to ward off suspicion of political maneuvers the committee decided to employ an expert engineer from Cornell University, but later reconsidered its determination. Of the four sites, it is intimated that the Comstock land has the preference with a majority of the committee.

Railway Surgeons' Convention.—The thirteenth annual convention of the New York State Association of Railway Surgeons was held last week at the New York Academy of Medicine, 21 West Forty-third street, with Dr. Henry Flood of Elmira, President of the Association, as Chairman. Dr. James A. Exton, of Arlington, N. J., discussed "Car Sanitation." Dr. C. B. Herrick, of Troy, N. Y., read a paper on the diagnosing of injuries to the head. Dr. Wisner R. Townsend, of this city, talking about "The Diagnosis of Injuries of the Hip," recommended that in diagnoses in children's cases the X-ray be used. Dr. Walter Lathrop, of Hazleton, Pa., sent a paper on "Modern Treatment of Wounds." In a paper by Dr. W. B. Coley, of this city, on "Traumatism as a Factor in the Causation of Hernia," the doctor said that his experience at the Hospital for the Ruptured and Crippled had shown that in only four cases out of 15,000 had hernia resulted from external accident. Dr. A. J. Gilbert declared that hernia had cost the railroad companies more money than any other cause of injury, and that it is a "frightful source of fraud, particularly among employes." The following officers were elected: President, C. G. J. Finn, Hempstead, L. I.; Vice-President, Dr. G. T. Conn, Concord, N. H.; Secretary, Dr. George Chaffee, Brooklyn, re-elected; Treasurer, Dr. J. K. Stockwell, Oswego.

Test for Diphtheria Antitoxin at Elmira.—Many new facts are likely to be brought out by the use of antitoxin in the rather severe epidemic of diphtheria now going on in the State Reformatory at Elmira. Over 50 cases have developed, including the assistant resident physician, and three deaths are reported up to the present time of writing. The entire supply of antitoxin in the city was bought up and appeals were made to the State. A supply of 1,500,000 units was received from the State Laboratory and every inmate in the reformatory inoculated. Resident Physician Christian and Dr. Frank W. Robertson, the Superintendent, have declared the epidemic completely and suddenly checked. Dr. Robertson said that antitoxin had made all inmates not already infected with the disease immune, and that the epidemic was completely under control, due to the antitoxin. All State medical societies have asked for a complete history of the cases, and it is likely that the results at the reformatory will figure in future literature relating to antitoxin.

The New York Medical Gymnastic and Massage Society.—This Society announces that after November 15 a clinic will be in operation under its auspices for medical gymnastic or massage treatment. Physicians often have patients of limited means for whom they would like to prescribe this treatment, were the expense not prohibitive. The proposed clinic will be a beginning in making a provision for the needs of

this class. Suitable rooms have been secured on the first floor at 210 East Forty-first street. Treatments will be given daily from 11 A.M. until 3 P.M., Saturdays and Sundays excepted, under the supervision of an Official Staff appointed by the Society. The treatments will be given by members of the Society, a sufficient number of whom will be present at each clinic hour. The same members are present at the same hour each day, so every patient will be treated throughout by the member to whom his case is at first assigned. Should any physician desire to put a patient under the charge of any particular member of the Society, an effort will be made to so arrange it, the member's time permitting. In order to provide for the maintenance of the clinic, in its essential expenses, patients will be charged an amount ranging from 25 cents minimum, to 75 cents maximum per treatment, according to their ability to pay. No free treatments will be given at the beginning unless by a vote of the Official Staff. The Society and its members give their efforts and time without remuneration. All receipts, either in fees or contributions, which may at any time exceed the amount necessary for the running expenses, will be devoted to increasing the facilities for work.

Three New Water Sources for City.—Three new sources of supply for increased water service for the city, each separate and distinct from the other, will be recommended within the next two weeks by the special commission appointed several months ago by Mayor Low to investigate the matter. The report was to have been submitted to Mayor Low Tuesday, but owing to the exhaustive investigation which the three Commissioners, Professor William H. Burr, Rudolph Hering and John R. Freeman, have made it has been impossible to complete it on time.

The commission will recommend that the city first acquire additional watersheds on the east side of the Hudson river, on the Upper Fishkill and Clinton Hollow, on the Upper Wappinger, in Dutchess county, establish a chain of enormous reservoirs, several of which will be much larger than the new Croton reservoir, and all to be connected by a line of aqueduct more than eighty miles in length. The commission will point out that by taking up this part of the work first the city will save the delay necessary to dig tunnels under the Hudson and bring water from the Catskill watershed. As soon as this work is under way the commission urges that the city should begin the purchase of property in the Ramapo region to get control of that watershed. The principal dam, they point out, should be built in the vicinity of Bishop's Falls, on the Esopus River, where it has been found that a dam of much greater height than has heretofore been deemed advisable may be constructed. This, the commission says, will make it possible to flood an area of more than fourteen square miles and provide a storage reservoir of more than double the size of the new Croton reservoir. In addition to this dam five others are recommended—viz., at Cold Brook, Lake Hill, Wittenburg, Shandaken and Big Indian. All of these are on the southern and eastern slopes of the Catskills. The commission proposes also to utilize the watersheds on the opposite side of the mountains and to turn the water into the Esopus by means of a tunnel thirteen miles in length, crossing under the Catskills from the Schoharie watersheds. Four sites for large storage reservoirs in the upper Schoharie watersheds have been located, so that this system will have a total of ten reservoirs large enough to hold in reserve the great supply of water which that region contains. Part of this supply will be utilized for Richmond Borough by extending the pipe lines through Jersey around by way of Paterson beneath the Kill von Kull. The third step to be recommended for bringing the supply up to the demand of the future New York is a filtration system in Dutchess county to purify the water of the Hudson river. A system capable of filtering fifty million gallons of water a day at the outset and so arranged that it may be increased from time to time is proposed. The entire report, covering all the details brought out by the extensive surveys and the thousands of borings made by the engineers sent out by the commission, and the estimated cost of the work, is to be sent to Mayor Low about December 1. It is now being printed, together with the maps and diagrams showing what work is necessary and just where each reservoir and pipe line is to be located. The completion of the first section of the work alone will require many years. After approval the scheme will undoubtedly be carried out under the direction of the Aqueduct Commission.

Mortality Rates in New York.—"A study of the ratio of deaths to population in this city by John F. Roche, made primarily for the life insurance companies," says the *Tribune*, "brings out a number of facts with which the general public is probably not well acquainted. To serve the special purposes he had in view his inquiry related to the bearing of sex and age, rather than that of disease, on length of life. In all respects the metropolis would not represent the country at large. The paper now reprinted from the 'Transactions of the Actuarial Society of America' was based on the census of 1890, and not that of 1900. Moreover, Mr. Roche refrains from philosophizing over the facts presented. None of these considerations, however, materially lessen the interest which attaches to his analysis. Possibly the most curious and novel feature of his statistics is the way in which first one sex and then the other exhibits superior vitality. Although a larger number of boys than girls are born here, the former appear to succumb more readily than the latter to the diseases and accidents of infancy and early childhood. At the age of seven Mr. Roche's tables indicate that a numerical advantage of about 1,000 in births has been wiped out, and thenceforward what has been regarded as the more tender sex continues to make the better showing for more than twenty years. Thereafter the pendulum makes two oscillations. Between the ages of twenty-nine and fifty-six men are—or were in 1890—more numerous than women. From that point onward the latter are again in the ascendancy. When the Eleventh Census was taken there were in this city 1,680 men who were seventy-five years old, and 2,120 women. For persons eighty-five years old or more the figures were respectively 201 and 518. The greater endurance in infancy and old age here revealed more than compensated for the higher mortality of women in middle life. The net result may be put in this fashion: Out of a population of about 3,500,000 there were at least 25,000 more girls and women than boys and men, and yet there were 5,000 fewer deaths among the former than among the latter. From this state of things Mr. Roche estimates that at the time of birth in this city the 'natural expectation of life' for a boy is thirty-nine years and for a girl forty-three. That an enormous proportion of children die before reaching the age of one full year is only too well known. It amounted to over 18 per cent. in 1890, or one death for between five and six births. A less familiar fact is the stage at which the minimum mortality occurs. The rate falls off rapidly with both

boys and girls from infancy to the age of eleven, when it is only one in about 440. Thereafter there is a steady increase. It slightly exceeds 1 per cent. at thirty, and 8 per cent. at three-score years and ten. About 20 per cent. of the women who attain the age of eighty-five, and 25 per cent. of the men, drop off inside of the next twelve months. Mr. Roche was able to make no comparison with the mortality of earlier years, but there is ample evidence from other sources that the average length of life in the United States has increased in the last quarter of a century. This results mainly from the adoption of sanitary precautions in large cities and from a better understanding of the nature of disease. Still greater progress, though, may be expected in coming years. Mr. Roche bases some of his hopes for the future in the metropolis on the filtration of water here. No doubt that will come in time, even if the death rate from typhoid fever remains as small as it is now. However, the greatest scourge is tuberculosis, which in 1900 caused 13.6 per cent. of the mortality in the metropolis. When the ignorant classes understand as well as do educated people what measures should be adopted to prevent infection with this disease a wonderful diminution of harm from it will result."

PHILADELPHIA.

Aged Negress.—Mary McDonald, a negress, celebrated her 133d birthday recently at the Home for Aged and Infirm Colored Persons. She did not know it was her birthday until she was congratulated by the matron and then said she did not wish to live much longer as she was too much bother to those around her.

Honor for Dr. Kirk.—The Dean of the dental department of the University of Pennsylvania, Dr. Edward C. Kirk, has just been notified that to him has been awarded the silver medal for the current year which the "Societe d'Odontologie de Paris" awards every year to the author of the best works published during the previous five years. The letter of notification from the Secretary of the Society closed as follows: "We desire to add to the good news herewith conveyed our heartfelt congratulations, and we further wish to inform you that the announcement to the Society of this just award was enthusiastically received."

Judge Determines Physician's Charges.—Judge Penrose, in the Orphans' Court recently, gave his views on physicians' charges when dealing with the estate of a spinster, who died in Atlantic City in 1902. He found a balance of $10,959.95 for distribution. One physician asked $350 for medical services, $400 for surgical services and $45 interest—$795 in all. "The claimant," said Judge Penrose, "was examined without objection to his competency. He testified that his practice was to charge from $3 to $5 a visit, the latter being the rate 'for people in good circumstances stopping at the better class hotels.' While the custom to charge persons supposed to have large means at a higher rate than the ordinary commercial value would not be illegal, in the opinion of the auditing judge the rate to be allowed for the day visits cannot exceed $3." This physician was allowed $434 for his services. A prominent surgeon who did a brain operation on the patient and charged $450 when he should have charged $1,000, was awarded $200 by the judge.

Women's Medical College.—A certain amount of discord is said to prevail between the above institution and the Women's Hospital which adjoins it and is used for the teaching purposes of the college. Although thus far the controversy between the two institutions has not been carried to the point where diplomatic relations are severed, it is feared that the latest move of the authorities of the college will make out-and-out strife inevitable. This comprises a proposition to build on the lot of land that separates the institutions a new hospital, to be under the control of the college. For this purpose the alumnæ have been asked to subscribe to a fund of $500,000. Friction between the two institutions started with an attempt on the part of the college to inaugurate an innovation, which, it was held, would destroy the identity of the hospital, lessen its usefulness and virtually make it an adjunct to its sister institution. A proposition was made that the various professors of the college be placed at the heads of their respective departments in the hospital. This arrangement was effective for a time but was finally discountenanced by the hospital authorities.

X-ray and Finsen Light Treatment.—The meeting of the Philadelphia County Medical Society November 11 was devoted entirely to the consideration of the above topics. Dr. M. K. Kassabian spoke on the Technic of X-ray Treatment. He exhibited cuts of a table which he has had devised for the Philadelphia Hospital. One advantage is that the patient can be treated from beneath as well as from above. Another feature is the diaphragm which is a sliding variety instead of an iris, as is usually employed. This table is so constructed as to protect both patient and operator. A mirror is so arranged that by looking into it the operator can watch the tube, regulate the light and observe the target without looking at the tube and thus affecting the eyes.

Dr. G. E. Pfahler reported very encouraging results in the treatment of carcinoma and tuberculosis. An interesting case was that of a retrobulbar sarcoma cured without affecting the eyesight. Dr. Pfahler finds that the more lesions have been tampered with before X-ray treatment has been begun the less likely are results to be secured.

Dr. W. M. Sweet, in discussing X-ray treatment of the eye and its appendages said that in epithelioma of the eyelid the older plastic operations were not now warranted since the X-ray was available. He has treated 30 cases with good results in all but two.

Dr. H. K. Pancoast, in the treatment of keloid by the X-ray, has found these growths amenable, but they require long and tedious efforts.

Finsen Light and X-ray in the Treatment of Diseases of the Skin.—Dr. J. F. Schamberg said that the use at the Philadelphia Polyclinic of the simplified lamp had not given results that made them at all enthusiastic. He believes that better results should have been attained by the 200 treatments in some cases. The simplified lamp does not penetrate sufficiently for deep lesions for which the Finsen lamp is necessary. As compared with X-rays these lamps are perhaps more useful in cases of lupus erythematosus. In lupus vulgaris the X-ray is better. In ulcerated areas due to lupus vulgaris the light treatment and the X-ray should be conjoined. The X-ray is better for mucous membranes and ulcerated areas and concentrated light for the skin.

The Cause of the Typhoid Epidemic.—Notes have recently been given regarding the belief of the officials that milk instead of water was responsible for the continued presence of typhoid in this city. Further investigations regarding recent outbreaks are in progress. As to their results up to the present Dr. A. C. Abbott says: "Between October 19 and November 12, inclusive, 55 cases of typhoid fever were reported from the Twenty-sixth and Thirty-sixth wards. Of this number 35 obtained their milk from

a single dealer. On investigation it was learned that between September 24 and October 5 and between October 5 and October 29 there had been two cases of sickness in the house of the dealer. These cases are represented to the Bureau as fevers—to be precise, as bilious remittent fevers—with some symptoms suggestive of typhoid fever, but not enough to justify a positive diagnosis and not enough to warrant their being reported as cases of typhoid fever. However, the Bureau decided to give the public the benefit of the doubt, and in consequence forbade the further sale of milk from the suspected premises. The house, the milk shop, and all utensils used in the business have been thoroughly disinfected. Had the Bureau received full information as to the possible nature of these cases at the time of their occurrence, much suffering might have been prevented. While it is dangerous to predict results, it is nevertheless the belief of the Bureau that an important factor concerned in the causation of a large number of the cases in the Twenty-sixth and Thirty-sixth wards has been discovered and eliminated. We regard the foregoing experiences as important arguments in favor of the position taken by the Bureau—namely, that too much attention cannot be paid to the sanitary conditions under which milk is supplied to the citizens."

Medical Jurisprudence Society.—On Monday evening, November 16, the Medical Jurisprudence Society of Philadelphia, after several years of inactivity, resumed its meetings, with Dr. Henry Leffmann, Secretary pro tem in the chair. Dr. Solomon Solis Cohen read a paper on "Judicial Determination of the Cause of Death." Dr. Cohen severely criticised the present system and considered the Massachusetts system, although by no means ideal, still an advance. He recommended a plan of which the following is a brief summary: (1) The cause of death to be determined by a jury of experts, consisting of a pathologist, bacteriologist, chemist, medical or surgical practitioner of admitted ability, neurologist, etc. (2) This jury, sitting in open court, be empowered to review the post-mortem, chemical, bacteriological and other examinations, hear testimony bearing upon the symptoms preceding and leading to death, review any evidence bearing upon the cause of death, and submit an opinion or opinions as to cause of death formulated in the shape of a report, or majority and minority reports, for the consideration of the lay petit jury before which the case will be tried. The paper was followed by an interesting discussion in which the lawyers very clearly indicated that Dr. Cohen's plan was not feasible under existing conditions, and the medical men present expressed the belief that it is doubtful whether a jury could be secured that would submit an unanimous opinion, and one lawyer believed that if such an opinion were submitted no jury would believe that it had been reached by legitimate and trustworthy methods. The Society will meet about four times yearly; the next meeting will be January 18, 1904, at which time permanent officers will be elected.

Medical Inspection of Schools.—A meeting of persons interested in this subject is to be held in Philadelphia, December 3, at 8 P.M., the place to be announced later in the daily papers. The meeting is for the purpose of aiding the plan of the Department of Health and Charities to institute a service of Medical Inspection of Schools, with School Nurses, in this city. The main address will be delivered by Dr. Ernst J. Lederle, Commissioner of Health, of New York City, who will be followed by the Supervising School Nurse of New York City, Miss Lina L. Rogers. The Mayor has consented to preside, and the President of our Board of Public Education will also speak. A discussion will follow these speakers.

CHICAGO.

Children's Hospital Commission Makes Report of Deeds and Needs.—Four months of philanthropic endeavor on the part of the Milk Commission of the Children's Hospital Society has reduced the death rate among infants and raised the standard of milk supplied to the homes of many thousands of both rich and poor. The Commission has given out the statement of its work and of its needs for the future. The funds it has on hand will keep it going until January. After that financial support must be forthcoming, but while this fact is set forth, no appeal for funds is made. The Commission prefers that its deeds should speak for it and determine to the public whether it is deserving of aid. Cases of poisoning of children by milk that was not fresh have been reported, and the blame is laid to the new rule of the Milk Wagon Drivers' Union, requiring but one delivery a day instead of two, as formerly. The drivers say, however, that under the old system the second delivery was old milk, shipped into the city at the same time as the first delivery. The Commission and the Union will now cooperate in an effort to obtain better transportation facilities, so that two daily deliveries may be had.

Praise from Dr. Reynolds.—Praise of the Commission's work comes from the Health Department. A letter from Commissioner Reynolds is made a part of the report, saying: "During the summer season there were 2,385 deaths of children under five years of age. This is at the rate of 12.6 per 10,000 of the total population. In the summer season of 1902 the proportion of such deaths was 13.3 and in that of 1901 it was 14.3. The reduction this year is especially significant in view of what was anticipated as a result of the one daily delivery plan. Children's physicians and sanitariums were gravely apprehensive of a murderous increase in child mortality through feeding of milk from forty-eight to sixty hours old. Fortunately this apprehension was not realized, chiefly, as I am firmly convinced, through the distribution of 190,000 bottles of sterilized milk by your commission."

Children's Hospital Society.—The organization of the Children's Hospital Society early last spring by the reform department of the Chicago Woman's Club is related, and then the creation of the Milk Commission, resulting from the discovery that out of 27 institutions visited by the Hospital Committee, not one was able to furnish its patients with milk of the desired standard. The Executive Committee of the Milk Commission is headed by E. P. Bicknell; Mrs. Geo. M. Moulton is Vice-Chairman, Mrs. Geo. W. Plummer, Secretary; Dr. A. B. Keyes, Auditor; and the other members are Drs. I. A. Abt and J. C. Cook. Dr. Frank Billings is the President of the Commission, and Mrs. Harold McCormick is Secretary.

Toy Pistol Ordinance.—The City Council passed a toy pistol ordinance Nov. 9, which prohibits the sale, loan or furnishing of toy pistols, guns, etc., to minors, and fixing a $100 fine for each offense.

Muzzling of Dogs.—The Chicago Medical Society, October 28, endorsed the ordinance now before the Council requiring the muzzling of dogs during the entire year. A committee was appointed to attend the Council and urge the passage of the ordinance.

The Work of the Milk Commission.—Mrs. Mary R. Plummer gave an outline of the work that this

Commission is doing before the Chicago Medical Society, Nov. 11, 1903. She referred to certified and inspected grades of milk, saying that there is no compulsory examination of cows unless there is complaint. Farmers who desire to furnish pure milk to the community do not object to having their cows and dairies inspected. She mentioned five farms which are under the inspection of the Commission. These farms furnish either certified or inspected milk. The inspectors of the Commission make periodical inspections and examinations of the dairies and cows of these farms, and if any one farm is not up to the standard exacted by the Commission, the inspector offers suggestions for improvement. Before milking the udders are wiped off, the milkman is compelled to have his hands thoroughly clean; the milk pail is thoroughly cleaned, and the first milk is discarded, because it is thought bacteria gather in it.

The Relative Importance to the Community of Pneumonia and Tuberculosis.—Dr. Arnold C. Klebs read a paper on this subject before the Chicago Medical Society, November 11, in which he drew the following conclusions: (1) That the relative economic importance of pneumonia and tuberculosis cannot be estimated by a mere comparison of total mortality figures for each disease. (2) That the high mortality figure and its increase of late, for pneumonia is produced by the enormous death-rate and its increase, attributed to this disease, in early childhood. (3) That, therefore, the high mortality from pneumonia and to a certain extent its increase is due to a classification of different ill-defined pathologic conditions under one name, while that from tuberculosis represents that of a well-defined morbid entity. (4) That for this reason and on account of the relative shortness of disabling sickness and frequent recovery in pneumonia, the great length of disabling sickness and infrequent recovery in tuberculosis, the relative importance of the two diseases is so vastly different, that a comparison on economic grounds reveals the overpowering danger from tuberculosis. (5) That the steady decrease of the tuberculosis death-rate can be explained on the grounds of increasing improvement of hygienic conditions in late years and as the result of specific prophylactic measures. (6) That the increase of the pneumonia death-rate occurring in a time of improving hygienic and sanitary conditions and of a general application of antiseptic principles, shows its independence of these features. (7) That, therefore, and in view of the still enormous mortality from tuberculosis, its demonstrated preventability and the possibility of its arrest only in its earliest stages, the institution of educational measures in regard to personal and public hygiene widely and specifically applied, for the prevention of this disease, seems to be distinctly indicated. (8) That since for pneumonia, as pointed out by E. F. Wells, "the fundamental information on which prophylactic rules may be formulated is not yet at hand" this subject needs further investigation from a bacteriological and epidemiological standpoint as well, before "exaggerated and irrational notions in regard to its dangers and its avoidance" are communicated to the public, which in view of the facts given are out of all proportion.

CANADA.

Appointments.—Dr. J. C. Mitchell, assistant physician at the Toronto Asylum for the Insane, has been appointed by the Ontario Government medical superintendent of the new Epileptic Hospital now in course of erection at Woodstock, Ontario. Dr. Mitchell is popular with the Ontario medical profession having been last year President of the Ontario Medical Association. He has been granted four months' leave of absence to visit similar institutions in the United States and Great Britain. Dr. M. O. Klotz of Ottawa, has been nominated by the Faculty of Medicine of McGill University for the appointment as Governor's Fellow in Pathology. Dr. Klotz is a graduate of Toronto University, and for some time past has been conducting experiments in bacteriology at the Ottawa Isolation Hospital. The appointment will be officially made at the next meeting of the Board of Governors.

Montreal General Hospital.—The following is the report of the Montreal General Hospital for the month of October: There were 250 admissions to the wards; 220 discharged; 12 deaths. In the outdoor departments there were 2,532 consultations, the largest number for any one day being 200. The number of ambulance calls for the month was 124. The typhoid fever cases have decreased to 24.

Toronto's Fine and Excellent Water.—That Toronto as a city has the purest supply of water of any city on the American continent is evidenced in the reports of the Medical Health Department on analyses made since July 11 last. On that date an analysis showed that there were 300 colonies per c.c. Most of the examinations made between that date and November 3 registered lower than 500. Only once did an examination register over 1,000. Ten years ago it was a common thing to have 20,000 colonies of bacteria per centimeter. The change is due no doubt to a new steel conduit and a new settling basin.

Ottawa Medico-chirurgical Society.—This society, which is the result of the amalgamation of the two old medical societies of Ottawa, held its first regular meeting on the evening of November 5, when the president, Dr. H. B. Small, delivered the first presidential address under the new order of things medically at the Capital. His address, which was very highly appreciated, referred to earlier medical history of the Capital, or Bytown, as it was formerly called. The society will meet the first and third Thursdays of each month. Sir James Grant, M.D., is the Hon. President; Dr. H. Beaumont Small, President, and Dr. C. H. Brown, Secretary.

British Columbia Marine Hospital.—Complaints have recently been made with regard to the condition of the Marine Hospital at Victoria, B. C., a hospital which by the terms of federation with the Dominion of Canada, the central government at Ottawa was bound to keep up and maintain in proper condition. The Victoria Board of Trade appointed a special committee to look into these complaints, with the result that the commission shows that the Canadian Government has sadly neglected the institution. Apparently the institution owes the Dominion Government nothing, but is in fact a money-maker. During the past five years ending June 30, 1901, the last returns which are available, $18,973.78 was paid for hospital dues by vessels entering at Victoria, while the amount expended during these five years upon the Marine Hospital was only $9,541.63, leaving a profit of $9,432.63.

British Columbia Medical Society.—The fourth annual meeting of the British Columbia Medical Society took place at Victoria, on October 30 and 31, with Dr. O. M. Jones of that city as president. A considerable number of physicians from the neighboring State of Washington was present and joined heartily in the various discussions. The president, in his annual address, dwelt upon raising the stand-

ard of medical education and that all should join in maintaining the noblest ethics of the profession. Among those who contributed papers were Dr. R. E. Walker of New Westminster, who read a paper on Pulmonary Embolism; Dr. Ernest Hall, Victoria, Deductions from the Study of Pelvic Disease in the Female Insane; Medical Ethics, by Dr. A. P. Proctor, Kamloops; Pathology and Treatment of Tuberculous Kidney, Dr. Eagleson, Seattle. The following were the officers elected: President, Dr. A. P. Proctor, Kamloops; Vice-President, Dr. Boyle, Vancouver; Secretary, Dr. Brydone-Jack, Vancouver.

Dispensary for Consumptives in Toronto.—With the concurrence of the medical profession of the City of Toronto, the National Sanitarium Association has decided to establish a free dispensary for outdoor patients in consumption. There will also be established in connection therewith a Medical Hall or Lecture Room, thus affording students full facilities for seeing and studying the disease in all its phases. The officers of the association also announce that the Free Hospital within five miles of Toronto is rapidly nearing completion. This will have accommodation for 50 patients, and when fully completed will cost $50,000.

GENERAL.

The Plague at Rio de Janeiro.—There were 23 deaths from bubonic plague and 66 fresh cases of the disease here during the past week. There are now 130 plague cases under treatment.

A Dispensary in the Desert.—The sanitary department of the Egyptian Government has received from Sir Ernest Cassel a gift of $100,000 for the purpose of establishing a traveling dispensary, constructed in tent fashion, but equipped with the most modern appliances. This dispensary will be transported to all parts of Egypt, including its most isolated desert places; and it is especially dedicated to ophthalmic work, the donor hoping thus to lessen the ravages of the ocular affections which are so widespread among the poor of Egypt.

Typhoid at Williams?—A disease which in some ways resembles typhoid fever exists among the Williams College students, and ten men are already prostrated with it. The physicians at first seemed to think that it was a form of grip, but they now say that it is a form of fever, although they will not admit it is typhoid.

Threatened Diphtheria Epidemic in New Jersey.—In their fight to prevent the spread of diphtheria in New Brunswick, N. J., the Board of Health of that city now find themselves confronted with a great obstacle. They have been expending money to check the disease and have exhausted their entire appropriation, with no prospects of getting any more money for six months. In the meantime there is a great danger of an epidemic of diphtheria. Already this month thirty-five new cases have been reported, while during the entire month of October there were only a total of five new cases reported at the office of the Health Board.

Warren Triennial Prize—Massachusetts General Hospital.—The Warren Triennial Prize was founded by the late Dr. J. Mason Warren in memory of his father, and his will provides that the accumulated interest of the fund shall be awarded every three years to the best dissertation, considered worthy of a premium, on some subject in Physiology, Surgery, or Pathological Anatomy; the arbitrators being the Physicians and Surgeons of the Massachusetts General Hospital. The subject for competition for the year 1904 is on some special subject in physiology, surgery, or pathology. Dissertations must be legibly written, and must be suitably bound, so as to be easily handled. The name of the writer must be enclosed in a sealed envelope, on which must be written a motto corresponding with one on the accompanying dissertation. Any clew given by the dissertation, or any action on the part of the writer which reveals his name before the award of the prize, will disqualify him from receiving the same. The amount of the prize for the year 1904 will be $500. In case no dissertation is considered sufficiently meritorious, no award will be made. Dissertations will be received until April 14, 1904. A high value will be placed on original work.

Cultivation of Protozoa.—At a meeting of the Kalamazoo Academy of Medicine held on November 3, Dr. F. G. Novy presented the results of work carried on, with the cooperation of Mr. McNeal, in the Hygienic Laboratory of the University of Michigan relative to the cultivation of the *Trypanosome* of Nagana or the Tsetse-fly disease of South America. They have succeeded in cultivating this flagellata, *in vitro*, for the past two months (68 days), through six generations. The fresh active cultures reproduce the disease in animals, modified cultures are without virulence and may possibly serve as vaccines. The method of cultivation is the same as that employed for the cultivation of rat trypanosomes, published in the Vaughan *Festschrift*. The rat and *Nagana trypanosomes* are the first pathogenic protozoa cultivated in pure condition outside of the body.

Yellow Fever in Laredo.—The official yellow fever bulletin last week was as follows: New cases, 20; deaths, 5; total cases to date, 768; total deaths, 77. Three new cases have been discovered at the Gannel coal mines, making the total number there 11. Two deaths from yellow fever occurred at Minera Monday, making a total of 10 deaths there to date.

Report of Texas State Health Officer.—Dr. George R. Tabor, the State health officer, has made the following report on yellow fever in Texas: "Actual conditions in Texas are as follows: About 700 cases, with 60 deaths, in Laredo; 18 cases, 8 deaths in San Antonio, with no cases reported in San Antonio for seven days; 5 cases, 2 deaths in Dewitt County. These are the only places of infection in Texas, and this is a true statement of existing conditions. Two frosts have fallen in Bexar and Dewitt counties. Conditions are favorable in Bexar, and I apprehend no further cases. The cases in Dewitt County are confined to one house, with no other house nearer than one mile. The disease is ended there. Laredo is well quarantined. There is no danger whatever to people coming to Texas, as our quarantine will amply protect other sections of the State."

The Huxley Memorial Lecture.—The fourth annual Huxley memorial lecture of the Anthropological Institute was delivered in the theater of Burlington House, London, by Professor Karl Pearson, F.R.S. The president of the institute, Mr. H. Balfour, occupied the chair. The lecturer's subject was "The Inheritance in Man of Moral and Mental Characters," a subject to which he has devoted many years of close and constant study, and the importance of which, as he observed, from a national point of view can hardly be exaggerated. It was a question of vital importance, he observed, as to how far mental and moral characters were inherited as compared with physical characters. Few denied the inheritance of physique in man, as in animals, but few too applied the results of such acceptance to their own conduct in life. We were agreed that good homes and good schools were essential to national prosperity, but were apt to overlook the possibility that the home standard was itself a product of parental stock, and that the relative gain from education depended to a surprising degree on the raw material. Since the publication of Francis Galton's epoch-making books it was impossible to deny *in toto* the inheritance of mental characters.

But it was necessary to go a stage further and ask for an exact quantitative measure of the inheritance of such characters and a comparison of such measure with its value for the physical characters. Accordingly he had some six or seven years ago set himself that problem, which really resolved itself into three separate investigations—namely, a sufficiently wide inquiry into the actual values of inheritance of the physical characters in man, and this was carried out by the measurement of upwards of 1,000 families; a comparison of the inheritance of the physical characters in man with that of the physical characters in other forms of life; and an inquiry into the inheritance of the mental and moral characters in man. In respect of this last set of investigations children were taken in schools of different sorts all over the country, and the opinions of teachers were asked upon the characters of their pupils in respect of the physical, mental and moral resemblances between brother and brother, sister and sister, and brother and sister. Six thousand circulars were thus sent out to about 200 schools. In respect of physical characters the data included the cephalic index—*i.e.*, ratio of the length to the breadth of the head, the span, color of eye and hair, curliness of hair, athletic power and health. In respect of all these the measure of the fraternal resemblance, indicated by the well-known regression line, was as two to one—that is to say, that if one of the pair exceeded the mean by a certain amount, the other of the pair tended to exceed the mean by half that amount; and similarly in respect of defect from the mean. This was always true for all the physical characters yet worked out in man. Now, seeing there was this surprising uniformity in the inheritance of the measurable physical characters, could these results be extended to psychical characters? Could we—that was the whole problem—get a corresponding regression line of two to one in steepness or slope in respect of mental and moral characters. A very large number of observations made on 1,918 pairs of brothers as to vivacity, assertiveness, introspection, popularity, conscientiousness, temper, probity, handwriting and general ability showed that while the line of regression was one to two or 50 to 100 in respect of physical characters, the smaller number was represented in respect of mental and moral characters by 51; while in respect of a large number of pairs of sisters it was 52, and these two numbers tended to approximate to 50 with an allowance for probable error. Hence there could be small doubt that intelligence or ability followed precisely the same laws of inheritance as general health, and both followed the same laws as cephalic index or any other physical character. There was a true line of regression in each case (.5 or 1 to 2), and it could safely be said that general health in the community was inherited in precisely the same manner as head-measurements or body-lengths. What results followed therefrom? By assuming our normal distribution for the psychical characters, there was found, in addition to self-consistent results, the same degree of resemblance between physical and psychical characters; and that sameness involved something additional—namely, a like inheritance from parents. We inherited our parents' tempers, conscientiousness, shyness and ability, even as we inherited their stature, forearm and span. Again, within broad lines, physical characters were inherited at the same rate in man and the lower forms of life. The irresistible conclusion was that if man's physical characters were inherited even as those of the horse, the greyhound or the water-flea, what reason was there for demanding a special evolution for man's mental and moral side? If the relation of the psychical characters to the physical characters was established, what was its lesson? Simply that geniality and probity and ability might be fostered by home environment and by provision of good schools and well-equipped institutions for research, but that their origin, like health and muscle, was deeper down than those things. They were bred and not created. It was the stock itself that made its home environment, and the education was of small service unless it were applied to an intelligent race of men. Our traders had declared that we were no match for Germans and Americans. There did seem to be a want of intelligence to-day in the British merchant, workman or professional man. The remedy was not in adopting foreign methods of instruction or in the spread of technical education. The reason of the result was that the mentally better stock in the nation was not reproducing itself at the same rate as of old; the less able and the less energetic were more fertile than the better stocks. No scheme of wider or more thorough education would bring up in the scale of intelligence hereditary weakness to the level of hereditary strength. The only remedy, if one were possible at all, was to alter the relative fertility of the good and bad stocks in the community. Grave changes had taken place in relative fertility during the last forty years. He ventured to think that we now stood at the beginning of an epoch that would be marked by a great dearth of ability. We had failed to realize that the psychical characters—the backbone of a state in the modern struggle of nations—were not manufactured by home and school and college; they were bred in the bone, and for the last forty years the intellectual classes of the nation, enervated by wealth or by love of pleasure, or by following an erroneous standard of life, had ceased to give us in due proportion the men wanted to carry on the ever-growing work of our empire, to battle in the fore rank of the ever-intensified struggle of nations. The remedy lay first in getting the intellectual section of our nation to realize that intelligence could be aided and be trained, but that no training or education could create it. It must be bred; that was the broad result flowing from the equality in inheritance of the psychical and the physical characters in man, and that result constituted a problem for statecraft to deal with.—(*Science*).

Death of William M. Warren.—In the death of William M. Warren, which took place last week in Detroit, not only the pharmaceutical, but the medical world has lost a very important figure. It is unquestionably true that Mr. Warren was the mainstay in the firm of Parke, Davis & Co., and through his influence has made the scientific pharmacy of this country what it is to-day.

Obituary.—Dr. McFadden Gaston died at Atlanta, Ga., last week of acute indigestion, aged seventy-nine years. He was prominent during the Civil War as a medical officer in the Confederate service. After the war, from 1865 to 1883, he made his home in Brazil, attaining distinction in his profession there. Since 1883 he had been at the head of the department of surgery in the Southern Medical College.

Dr. Charles Marshall, a prominent physician of Huntingdon, Province of Quebec, Canada, died suddenly of apoplexy at 272 West One Hundred and Seventeenth street, on Friday last. Dr. Marshall had arrived in New York two hours before to make a visit to his relatives here. Mr. Moore met him, and at his home he was served with a light luncheon. The attack of apoplexy followed, and was almost immediately fatal. Dr. Marshall was a graduate of New York University, and practised for several years in the hospitals of Paris and Edinburgh, later settling for practice in Huntingdon, his birthplace. He was a member of the Medical Board of Governors of the Province of Quebec, and was prominent in the Masonic Order.

Dr. Hortense A. Miller died at Bellevue Hospital on

Nov. 9, from illness contracted six years ago while she was nursing yellow fever patients at New Orleans. A descendant of the Earl of Clarendon, Mrs. Miller was born in Boston fifty-one years ago, her father being Eliphalet Hamlin and her mother Katharine Hardy, both well known during their lifetime in Boston. She married Edward Miller, a wealthy Boston man, and traveled about the world with him till he died, eighteen years ago. Then she went to the University of Michigan, at Ann Arbor, where she was graduated as a physician, and afterward gave her services and her money wherever they could do the most good.

Dr. George J. Engelmann, one of the best-known gynecologists in the country, died suddenly November 16, from pneumonia. He was born in St. Louis fifty-five years ago, but had lived in Boston for the past six years. Dr. Engelmann was born in St. Louis July 2, 1847. His father was Dr. George Engelmann, and his mother before her marriage was Dora Horstmann. He was graduated from Washington University in 1867. From 1867 to 1873 he studied medicine at Tübingen, Germany, where he took his degree of M.D., and also at the University of Vienna. During the Franco-Prussian war, 1870-71, Dr. Engelmann practiced surgery. From 1873 to 1895 he pursued his profession in St. Louis. In later years he was in Boston, pursuing his specialty. Dr. Engelmann was an extensive traveler, and was deeply interested in archæological and ethnological researches. His collection of Missouri flints and pottery is now in the Peabody Archæological Museum at Cambridge, Mass. He was a professor in the Post-Graduate School of Medicine in St. Louis and the Missouri Medical College until 1894. He was accorded high honors by his colleagues at international meetings of surgeons in Brussels, Amsterdam and Rome.

SOCIETY PROCEEDINGS.

THE JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held October 12, 1903.

Dr. Thomas B. Futcher was elected president and Dr. C. P. Emerson secretary for the coming year.

Demonstration of Medical Cases.—Dr. McCrae said he desired to show the pathological specimens of a case which had several admissions to this hospital before death. The patient was a colored man, forty-nine years of age, and was admitted complaining of shortness of breath. Three months before admission he had "caught cold" and was still suffering from cough and pains in the chest. Examination showed a lift of the manubrium and an area of dulness in the chest. A diagnosis of aortic aneurism was made. On his second admission he showed the same symptoms, and examination revealed a large pulsating swelling reaching from the second to the fourth rib and far out to the right from the sternum. There was no pulsation or prominence to the left. Suddenly, however, the fulness one day disappeared from the right and appeared on the left. Ten days later the tumor again moved to the right and the heart apex, which had moved far out toward the axilla, came in again toward the middle line. On the third admission the patient showed signs of adherent pericardium and of aneurism on the left side of the sternum. Shortly after his entrance to the hospital the tumor once more moved to the right, where it remained until death. The specimen from the case is that of an anuerism of the aortic arch one inch above the valve. The portion on the extreme right, which corresponds to the area where the pulsating tumor first appeared, is very thin. The pericardium and lungs are very adherent. There is erosion of the trachea, a second small aneurism on the descending arch and a general diffuse bronchiectasis of the left lung. The thinness of the right wall of the aneurismal sac may explain the peculiar change in the physical signs noted before death. The shifting of the tumor, however, might also be explained by the relation which the aneurism bears to the heart, particularly when it is remembered that the heart apex shifted markedly during life. Pressure of the aneurism on a bronchus, with resulting changes in intrathoracic conditions, might also explain the phenomena. Death was due to rupture of the pericardium. X-ray photographs showed a shifting shadow corresponding to the change in the physical signs.

Demonstration of Surgical Cases.—Dr. Follis exhibited the first patient, a woman, aged forty-five years, who was brought to the hospital with a wound in the right lumbar region caused by a 38-caliber revolver. Her last meal had been taken four hours before admission and she was seen two hours after the accident. Examination showed abdominal rigidity, normal temperature and leucocytosis of 30,000. The abdomen was opened through the right rectus and the cavity found full of bloody fluid and bowel contents. Eleven intestinal and 6 mesenteric perforations were found. Two in the cecum and two in the ileum were closed. The portion of gut containing the 7 remaining perforations was excised and the two bowel ends left in the abdominal wall. Patient reacted well and her condition was good for two weeks, but on account of her failing nutrition (due to the loss of fluid matter through the high fecal fistula) an extraperitoneal lateral anastomosis was done by the elastic ligature method. Patient did well and after six weeks the bowel ends were excised and turned in under cocaine. The second case is a colored boy aged ten years, who was admitted with typical signs of peritonitis and of typhoid fever, including a positive Widal. He was immediately explored and an intestinal perforation found about 25 cm. above the ileocecal valve. The ends of the bowel were brought to the abdominal wall and left there. The patient had a postoperative pneumonia of the right side, developed a large abscess of the right thigh, subsequently suffered acute intestinal obstruction due to the omentum and was sick with the measles for one month. The enterostomy wound was finally closed under cocaine and the patient recovered completely. Enterostomy in general peritonitis with distention is not a new procedure, having been done by Coyen of Paris; and from one of the Vienna clinics we are told that a typhoid perforation should never be closed as a rational avenue for drainage.

Dr. McCrae said that Dr. Follis' second case teaches plainly that a typhoid patient should at least have the chance of an operation even when general peritonitis has fully developed. The statistics of this hospital show that about 33 per cent. of the cases recover with operation.

Ascending Renal Infection, with Special Reference to the Reflux of Urine from the Bladder into the Ureter as an Etiological Factor in its Causation and Maintenance.—This was the text of Dr. Sampson's paper, who said that in radical operation for uterine cancer the question arises, What should be done with the ureter? and to answer this one must understand the pathology of kidney infections. There are three avenues of infection of the kidney. First, the blood vessels. Experiments in dogs, in which the ureter was ligated, have shown that pyonephrosis may develop from the injection of staphylococci into the injured bladder; and hence a hematogenous ascending renal infection is a possibility. The anastomosis between the renal, uterine, ovarian and vesical arteries offers also a chance for blood infection of the kidneys. Organisms may, in

addition, enter through the ureteral artery which connects directly with the renal circulation. Second, the lymphatics. Dr. Sampson's experiments on this point have been negative. Third, the lumen of the ureter. The anatomy of the intravesical portion of the ureter shows that its oblique course through the bladder wall and the prolongation of its anterior lip to form a valve, offer, in the distended bladder, a natural obstacle to the back flow of urine. In a contracted bladder, however, the course of the ureter is less oblique, the ureteral valve is less prominent and the prevention of reflux is due to a puckering of the bladder mucosa. The state of distention or contraction of the bladder changes the ureteral orifice and consequently the chance of a reflux of urine. My experiments and cystoscopic examinations show that the ureter undergoes contraction so long as fluid flows through it and that the ureteral orifice draws back just after the expulsion of the urine stream into the bladder. Infection may reach the kidney by way of the ureter from the following causes: (1) Injury to the ureteral orifice. He has had several clinical cases in which infection has probably taken place in this way. (2) By extension of the inflammatory process from the bladder wall. This is most frequently the case. One of his patients developed a renal infection from a cystitis due to a retention catheter. (3) Motility of organisms. (4) Backflow of urine, which may be caused either by increased bladder pressure or reversed peristalsis. The experiments on this subject are somewhat contradictory, but I believe that urine flows back through the ureter only when there is disease of the ureteral orifice. Experiments, clinical observations and autopsy findings warrant this assertion. His work leads him to believe that indiscriminate hydraulic distention of the bladder for cystitis is a dangerous procedure, and that ureteral catheterization through an infected bladder should not be done. The most rational treatment for cystitis is the formation of an artificial vesicovaginal fistula which rests the bladder and cures the ureteral stricture. A retention catheter is a dangerous instrument, because it may act as a foreign body. A study of the anatomy and pathology of the ureter shows that this tube not only carries urine from the kidneys to the bladder, but is also of value in absolutely preventing flow in the other direction.

Dr. Russel said that Dr. Sampson's work has many practical sides. Cystitis is the bête-noir of gynecology and this paper has told a great deal about its etiology.

Dr. Young said that he reported some experiments as to the presence of the ureteral reflux in the cadaver and in dogs. Many severe cases of cystitis were, at this time, treated on the surgical side of the hospital by the method of distention—after the safety of this procedure had been demonstrated experimentally on dogs. The results were uniformly good—in one case remarkable. In the past six years he has treated many contracted bladders by hydraulic distention without a sign of ureteral reflux and no symptoms of renal infection. In the Musée Guyon, last summer, he found one case of ureteritis in which the orifice of the diseased ureter was wide open and in this case the fluid would unquestionably flow up the ureter, just as Dr. Sampson has demonstrated in two of his patients. In such cases, however, the kidney and ureter are already diseased and in Dr. Young's opinion the upward flow of any antiseptic fluid would cause no additional injury but might be of benefit, being analogous to Dr. Kelly's method of irrigating the pelvis through the renal catheter. He is glad that Dr. Sampson has come to the same conclusions he himself reached and has also taken his stand against the work of several European investigators, who have attempted to show that a ureteral reflux may be present in normal cases. If hydraulic distention is given up, because of rare ureteral disease, a miserable class of unhelped patients is left.

Dr. Hunner said he has seen a case of what was apparently renal infection following closure of vesicovaginal fistula. Possibly in this patient the bladder became distended during sleep and a reflux of urine took place. Another patient of his, with a stricture of the ureter has frequent attacks of renal infection, which always occur at night—possibly for the same reason.

Dr. Sampson said that in the autopsy room in ordinary cases it is, as Dr. Young says, impossible to force urine from the bladder through the ureteral opening, but by hardening the orifice with formalin, thus simulating ureteral disease, he has been able to cause a reflux.

Stated Meeting, held October 26, 1903.

The President, Thomas B. Futcher, in the Chair.

Some Recent Cases of Extra-uterine Pregnancy.—Dr. Cullen said that extra-uterine pregnancy has recently, in the Johns Hopkins Hospital, been more frequent than usual; and probably many cases have in the past been overlooked. The first patient was a woman of thirty years, who was nursing her child and hence gave no menstrual history. The symptoms were pain in the left side, absence of temperature and a palpable mass which was movable. She made a good recovery after operation. The second patient had no symptoms until a sudden collapse and two similar attacks several weeks later. There had been no hemorrhage and no temperature. The pelvis was found full of blood. The third patient showed the classical symptoms of collapse, pallor, distention, hemorrhage and a palpable mass. The fourth and fifth cases were characterized by labor-like pains, and in the last patient of the series the diagnosis was somewhat difficult because she was at the time nursing a ten-months' child, and the mass in the pelvis suggested a myoma. The pathological specimens from these cases showed both extremes of tubal distention.

Dr. Osler said that these cases are often seen at post-mortem and some years back the diagnosis was practically never made, tubal pregnancies being always called pelvic hematoceles.

Dr. Cullen said that careful descriptions of this condition occur in the French literature before 1800, but Lawson Tait was the first to call careful clinical attention to extra-uterine pregnancy.

A Case of Typhoid Arteritis.—This subject was introduced by Dr. W. R. Steiner. The patient was a boy aged nine years. He complained of headache and weakness, but had had no nose bleeds, nausea, vomiting or diarrhea. His temperature was 101.8° F., pulse 100, Widal reaction negative. Rose spots appeared later and the spleen became palpable in three days. On the twenty-second day of the disease the temperature had fallen to 99.2° F. The next day, however, it reached 103.8° F. and there were all the symptoms of a relapse, with marked delirium, but the temperature reached normal on the thirty-ninth day. On the forty-first day numbness and tingling of the right index finger appeared and gradually the pulse diminished in the right radial artery. There were tenderness, hardness and redness along the vessel and the hand was cold and cyanotic. The fever ran a most discouraging course, bronchitis, a relapse and marked emaciation with delirium being the untoward features. The cyanosis of the arm, however, gradually disappeared and thirty-five days after onset of the arteritis the pulse returned in the right brachial and axillary arteries.

Dr. Thayer said that several similar cases have been reported from the Johns Hopkins Hospital. In one patient the left femoral was involved and in another

an arteritis of the middle cerebral artery was found post mortem. One patient, a girl of eight years, suddenly became unconscious and showed rigidity of the neck with a typical syndrome of Weber, since which time she has had attacks of Jacksonian epilepsy pointing to thrombosis of a cerebral artery.

Dr. Futcher said that Keen collected in his monograph 115 cases of arterio thrombosis and 46 cases of subsequent gangrene.

The Treatment of General Infections, with Especial Reference to the Use of Silver Nitrate in Such Cases.—This was Dr. Joseph Hume's subject, who said that the surgical treatment of general infection aims at free drainage, stimulation and increased elimination. The injection of salt solution, the administration of antitoxines and the introduction of antiseptics into the blood illustrate these fundamental principles. It has often been observed that infection causes a rise in the leucocyte count. It, therefore, seemed that possibly an effort artificially to increase the white blood count was indicated. Silver nitrate has this effect and hence it has been used in the treatment of infections. Possibly it does good by destroying the blood corpuscles and setting free antibodies. If so, a new principle in therapeutics has been established, namely the introduction into the blood of a hemolytic agent. In the series of cases here reported one c.c. of a 10-per-cent. solution of silver nitrate was mixed with 1,000 c.c. of water. Of this mixture 500 c.c. was injected intravenously at a temperature of 110° to 115° F. A chill, rise in temperature, marked drop in the leucocytes, followed by profuse sweating were the phenomena observed in all cases. Several characteristic cases were reported. The first was a girl, aged 16 years, suffering from streptococcus infection following an appendectomy. The usual surgical treatment did no good, the patient became extremely toxic, but following two injections of silver nitrate recovered completely. The second was a patient with a large peritoneal abscess, probably a general peritonitis. She was weak and irrational, and became rapidly worse in spite of treatment. The temperature had reached 104° F. Silver nitrate was given three times with the usual subsequent phenomena. After each injection there was some improvement and the patient was finally discharged well. Another case of streptococcus infection, very toxic and delirious, was similarly treated and after the third injection made a perfect recovery. Ten cases of pyogenic infection have been treated by Dr. Hume with silver nitrate. He has had but one death and that from intercurrent infection. No local results have been observed except two cases of mild phlebitis.

Dr. Pancoast said that Dr. Hume's cases had all been given up, so his material was not promising. The destruction of blood is the only result which silver nitrate has in common with salt solution and formalin, hence this may explain the effect of these agents in infections.

Dr. Thayer said that there is nothing in the literature to support the theory that destruction of leucocytes sets free antibodies. The relation between leucocytosis and prognosis was long ago made the basis of treatment by the administration of turpentine in pneumonia. The reappearance of an excess of leucocytes is according to Weigert's law of the tendency of the human body to overproduction. Theoretically it is poor therapeutics to attempt to destroy the blood of a patient whose powers are already being severely drained. Practically this method of treatment has apparently done some good, but very positive experimental evidence is necessary to make it of general use.

Dr. Cole said that it should be remembered that many cases of streptococcus infection recover without treatment. In a series of 49 cases of general infection, 19 from which the streptococcus was isolated, got well; and this summer in the Johns Hopkins Hospital a patient desperately ill with streptococcus infection suddenly began to improve and made a perfect recovery.

Dr. Emerson said that ordinary salt solution, even though not perfectly isotonic, is *not* hemolytic. Hence it does nothing but good to the blood corpuscles. The blood therefore is not laked and the apparent destruction of white blood corpuscles is really only a leucopenia. If blood were actually destroyed by silver nitrate injection restoration would not be so rapid as it has seemed to be in Dr. Hume's cases.

Dr. Reik stated that one of the cases in Dr. Hume's series had come to him first with a general infection following thrombosis of the lateral sinus. Patient was *in extremis* and had been given up, metastatic abscesses having already formed. Improvement and recovery followed the use of silver.

Stated Meeting, held November 2, 1903.

The President, Thomas B. Futcher, in the Chair.

Exhibition of Medical Cases.—Dr. Cole presented three cases of typhoid fever with meningeal symptoms. The first patient showed contraction of the neck and muscular rigidity and typhoid bacilli were isolated from the cord. In the second case lumbar puncture was done with subsequent improvement. From the spinal fluid which was under tension typhoid bacilli were isolated. Later they were obtained from the blood; and, following a furunculosis, staphylococci also appeared in the blood. This is the only case of secondary blood-infection which has occurred during typhoid fever in the Johns Hopkins Hospital. The third patient had a severe attack of typhoid with bronchitic and meningeal symptoms. Typhoid bacilli were isolated from the spinal fluid. Cases of prolonged fever with nervous symptoms should always make one think of typhoid fever and lumbar puncture is indicated.

Dr. MacCallum showed the pathological specimens of the third case reported by Dr. Cole. There was a distinct exudate over the brain and cord. The gall-bladder was distended, covered with exudate, filled with a suspension of typhoid bacilli and in two places had perforated. This feature would seem to indicate that operation in typhoid cholecystitis is indicated.

The Late Effects of Typhoid Fever on the Heart and Blood-vessels.—Dr. Thayer reported the results of his studies made during the past two years on the vascular features of typhoid fever. The acute vascular conditions such as thrombi, etc., are well enough known, but the relation of typhoid to arteriosclerosis has never been fully worked out. Landouzy, however, holds that typhoid fever is next in importance to rheumatism in producing angiocardiac changes. Dr. Thayer had examined 182 patients who had had typhoid fever from one month to eighteen years previously. In 60.4 per cent. the pulse varied from 60 to 90 and in 30 cases it was somewhat irregular. The blood-pressure was in all cases somewhat high, and over 50 per cent. of the cases over twenty years of age showed palpable arteries. A series of observations was made on the blood-pressure of 276 normal individuals and the average was somewhat lower than in patients who had had typhoid fever. In another series of observations in normal individuals the percentage of palpable arteries was also somewhat smaller than in the typhoid cases; 46.4 per cent. of the cases showed cardiac murmurs, 6 patients having mitral insufficiency and one showing the rare condition of aortic functional disease. Eighty-two cases showed reduplication of the second sound and there was one case of mitral stenosis and one of marked arteriosclerosis.

Dr. Emerson reported an analysis of a thousand cases of albuminuria and stated that his study confirmed Dr. Thayer's opinion of the effect of typhoid fever on the arteries. Strange to say, however, the analysis shows that it has not much effect on the kidneys though the opposite would be expected. Dr. Thayer called attention to the fact that albuminuria is almost constant in typhoid fever, but however bad the urine, the clinical symptoms of nephritis are rarely seen.

Dr. Reik reported a new remedy for tinnitus aurium. The origin of this condition has never been clear though it has been supposed to be due to an increase in intra-labyrinthine pressure and resultant stimulation of the auditory nerve. Dr. Reik's experiments on dogs showed that any irritation of the sensory nerve in the ear caused a depressor effect which is contrary to the usual law. These results confirm Dr. Theobald's theory that tinnitus aurium arises from vibrations starting from the blood-vessels. With the idea of raising blood-pressure suprarenal extract was employed by Dr. Reik both locally and internally. Thirty-five cases were reported cured, most of them rapidly, 15 were improved and only one showed any bad effects.

Dr. Burnam showed the pathological specimens of four rather unusual appendices. The first was from a colored woman aged twenty-eight years who had had an abdominal tumor without temperature. And abscess with infiltrated walls formed in the abdominal wall and scrapings from it showed large numbers of the ray fungus. At the second operation the appendix was found to be the cause, death ensued and at autopsy the appendix showed marked submucosal thickening. There were abscesses also in the lungs. An interesting feature of the case was that the leucocytes never rose, though the temperature reached 106° F. A case of primary carcinoma of the tip of the appendix and two cases of primary tuberculosis of the appendix were also shown and Dr. Burnham stated that these cases gave one more reason for the need of early operation, even in chronic appendicitis inasmuch as the appendix in these cases may be the site of some very severe condition.

NORTHWEST MEDICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, held October 6, 1903.

The President, A. C. Buckley, M.D., in the Chair.

Lobar Pneumonia, Delayed Resolution, Recovery. Hemiplegia, Partial Recovery.—This paper was read by Dr. Harry Lowenburg, in which he reported the case of a boy, seven years old, giving a negative family history, with the exception that his father was an alcoholic and that there was some evidence of Bright's disease on the paternal side. His previous personal history was good, excepting that he had suffered from an attack of varicella a few weeks previous to his present illness, which began with fever and general prostration, and the attending physician diagnosed as typhoid, and when he was admitted to the hospital three or four days after the beginning of the attack he had a temperature of 104° F.; pulse 124, and respirations 24. There was the usual phenomena attendant upon marked febrile movement, slightly coated tongue, constipation, restlessness, hyperesthesia and exaggerated reflexes, but physical examination of the lungs, heart, liver and spleen was negative; there was no tympanitis, and no skin eruption and the Widal and diazo reactions were negative. The following day the respirations had increased to 44 and the pulse to 140, and there was complete dulness and vocal resonance and vocal fremitus over the right intrascapular space and over the anterior aspect of the right apex, at which time a diagnosis of acute lobar pneumonia, involving right apex and entire posterior aspect of the right lung, associated with dry pleurisy, was made. At 3 A.M., on the day following his admission, the temperature fell from 104½° to 98⅘°, F., the pulse and respiration remaining at their previous rate, and the temperature rising to 105° F. at 6 P.M. At this time a blood examination showed red blood cells, 3,100,000; white blood cells, 15,000; hemoglobin, 62 per cent. His temperature continued high until about twenty days after his admission, when it fell to normal, and at this time for about three days he had slight hemorrhages from the lungs. A few hours following the fall in temperature there was complete palsy of the right arm and leg and right side of the face in the lower half, although he could open and close his right eye, and there was incontinence of urine and feces. For three weeks his condition remained about the same, although the auscultatory signs of consolidation improved somewhat. Several exploratory punctures were negative and the sputum showed absence of tubercle bacilli. Gradually the pneumonia disappeared, his appetite improved and he was placed on solid diet, and about six weeks after the beginning of the attack was sent to the country in a weak and emaciated condition, still suffering from incontinence of the feces and urine. He was ordered plenty of fresh air, sunshine, electricity, massage, inunctions of blue ointment, and KI, grs. v., and bichloride, gr. ½, t.i.d, and four weeks later he was able to move his arm and leg somewhat, and at the present time, about five months and a half after the commencement of the attack, is able to walk, although showing considerable defect; can raise his arm almost as high as his head; his face still shows some slight effect, although his speech is apparently perfect and his bodily nutrition has improved. There is still drooping of the right shoulder and restricted movement of the right chest, probably due to pleural adhesions. The author felt that the hemiplegia was due to an embolism, probably originating from the resolving lung.

Dr. Luther C. Peter referred to the fact that hemiplegia occurs considerably in the infectious fevers, particularly typhoid, coming on usually during convalescence, when the circulation is exceedingly slow, and being usually due to a thrombosis. In the present case, however, he felt that the sudden onset pointed to an embolism.

Dr. J. Thompson Schell felt that both the symptoms and the sequelæ pointed to embolism.

Dr. M. P. Warmuth reported a case of lobar pneumonia of the right lung, occurring in a child, in which during the last week of the convalescence the child was entirely blind, lasting a week or ten days, after which the symptoms entirely disappeared, the temperature range being similar to that reported by the author. He felt that the case reported was caused by an embolism, and reported a case following diphtheria, in which there was complete paralysis of the right side for six to eight hours, and for the following thirty-six hours the right radial pulse could not be felt, after which, however, it returned.

Dr. A. C. Buckley reported the work of a German observer, who had recorded seven cases of hemiplegia following infectious fevers, excluding pneumonia and scarlet fever, all followed by autopsy and showed no meningitis present, the condition being attributed to change in the blood-vessels.

A Case of Ludwig's Angina.—This paper was read by Dr. C. M. Harris, in which he stated that the disease was generally supposed to be a streptococcus infection about the submaxillary gland and alveolar tissue, beneath the mucous membrane in the floor of the mouth, as a result of which there is cellulitis about the gland

tending to sloughing rather than pus. The symptoms are local discomfort, followed in from two to four days by swelling and pain; pressure causing considerable dysphagia and sometimes salivation and dyspnea. In some cases there is a high temperature and symptoms of septicemia, pyemia, or even gangrene, may be present. The treatment should consist of prompt incision and removal of any gangrenous tissue, followed by the application of carbolic acid and constitutional treatment, as indicated for septicemia. He reported a case in which a patient had gone to a public bath and remained in the water for two to three hours, and the following day complained of some pain in the right ear and some swelling in the right submaxillary region. The symptoms increased and on the third day there was a hard, tense swelling in the submaxillary region about the base of the tongue which was unattended by external redness or any heat. It was difficult to open the mouth and there was a thick coating on the dorsal surface of the tongue and some of the buccal mucous membrane. There was edematous swelling about the frenum and the submaxillary and sublingual ducts were quite prominent. The temperature was 100° F. On the evening of the fourth day the swelling had extended posteriorly, beyond the angle of the jaw, and the pain in the ear was almost intolerable. An opiate was given, under the influence of which the patient passed a comfortable night. On the fifth day the swelling and pain began to diminish and on the seventh day had practically disappeared, the tongue cleared, the mouth could be opened fully, and presented nearly normal appearance. On the ninth day there was a discharge of pus from the affected ear, which continued for about a week, when it ceased and the patient has since enjoyed good health. The constitutional treatment consisted of quarter-grain doses of calomel hourly for eight to ten hours during the first four days of the disease, and local applications of peroxide of hydrogen and other antiseptic solutions.

Dr. Justice Sinexon reported a case of cervical cellulitis, occurring in an engineer, whose run required him to be absent for two days each trip. On the way out one day he noticed that his neck was stiff, and the following day he presented all the symptoms of the "stiff collar" appearance of the neck. He had much difficulty in swallowing and speaking, and the swelling was most marked at the angle of the jaw. He was given one-tenth-grain doses of calomel every hour for four or five days. On the fifth day an incision was made in the floor of the mouth without any result, which, after the application of belladonna ointment, was followed by the discharge of a small amount of pus and the man made a good recovery.

Dr. William L. Pepper referred to the frequency of the occurrence of cellulitis during epidemics of influenza, as well as in cases of peridermitis, which he ascribed to the infection traveling through the glands.

Dr. T. Turner Thomas reported a case in which the incision had been made on about the seventh or eighth day of the disease, followed by hot applications of bichloride. The patient had considerable dyspnea, which increased after the operation, and during a severe attack, a tracheotomy was attempted, but before it was performed the patient died. He felt that the danger in this condition was principally due to the fact that it involved the deep structures, the least resistance being in the direction of the mouth and throat. He recommended the employment of early free incision, and believed that the prognosis was also dependent upon the kind of infection.

Dr. Harris, in closing the discussion, said that there was probably some danger in the conservative treatment, and that radical measures were probably the surest means.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held at the New York Academy of Medicine, October 12, 1903.

The President, Andrew H. Smith, M.D., in the Chair.

Vacation Odds and Ends.—The President, Dr. Smith, gave some observations at the International Medical Congress, at Madrid, and elsewhere in Europe during a trip from which he had just returned.

The Fourteenth International Congress.—The success of the Congress, he said, was all that could have been expected under the existing conditions. In the midst of so many counter-attractions, it was no wonder that science fared rather ill and that the central idea of the meeting was measurably lost sight of, while its festal side assumed undue prominence. A serious obstacle to the success of international gatherings in general was especially accentuated in this. At the Congress held at Rome there were four official languages; at the Madrid Congress Spanish was necessarily added, and as rather more than one-half of all the congressists were Spanish, it followed that three out of every five papers were in that tongue, the least understood by foreigners. It seemed to him that in future the official language would have to be restricted to one or two of those most generally understood, or the whole scheme of international congresses would degenerate into a Babel which would result in its abandonment. At the opening of the Congress 1,681 papers were announced on the official program. These were apportioned among 16 different sections, making an average of 105 to each section. Of course, this meant that by far the greater number could be read by title only, and many did not receive even this scant measure of recognition. Dr. Smith thought it would be better if in the future a strict censorship were exercised by a committee of the best available men, and only a relatively small number of the highest class of papers admitted to a place on the program. At present all papers presented were accepted.

Medical Education in Italy.—The degree of M.D. is conferred by 17 universities and by the Royal Institute of Florence. The course extends over a period of six years, and cannot be shortened by extra diligence and application. A large amount of scientific work is done in the laboratories of the universities, and much of it is of a very high quality. At Rome there are about 650 medical students. The amount of clinical material is very great, but its utilization is at present handicapped by antiquated buildings very imperfectly adapted to teaching purposes, the magnificent new Policlinico being still uncompleted. Rome, formerly considered one of the most unhealthy cities in the world, presents now a death-rate smaller than that of New York. (In 1902, 16.9.) This has been effected (1) by restraining the Tiber between embankments and (2) by increasing the water supply, which comes from an unimpeachable source in the Alban Hills, and at the same time summarily filling in the polluted wells.

The Allgemeine Krankenhaus in Vienna.—This, the largest hospital in the world, with 4,000 beds, comprises a large number of buildings, none of which are modern. Modern requirements have been met as far as possible by alterations and adaptations, but the only possibility of bringing the institution into line with the demands of the day is by demolition and reconstruction. The Vienna Polyclinic, though more modern than the Krankenhaus, seems to American eyes much behind the times; we miss the appearance of neatness and absolute cleanliness to which we are accustomed. In one respect there is a decided lack: the nurses are not trained up to our standard, and the evidences of slovenly work are apparent on every hand. This was more or less true,

indeed, in all the hospitals Dr. Smith has seen in Europe. Nevertheless, as all the world recognizes, excellent work is done in the hospitals and clinics of Vienna. A low valuation of life appears to prevail in the public institutions, and this impressed him particularly at the Polyclinic, where patients and cadavers seemed to be regarded in much the same light as "teaching material." He learned from an American nurse that she was told, in answer to her inquiry, that diphtheria antitoxin was seldom used in the children's hospitals, as it was too expensive.

Finsen's Clinic at Copenhagen.—The building was erected expressly for this purpose about three years ago, and its main feature is the great operating room, in which are 27 tables for the accommodation of patients while undergoing treatment with the Finsen light. These tables are fitted up with every form of adjustment that can make the patient more comfortable during the application, which lasts from an hour to an hour and a half. Prof. Finsen observed that the effect of the rays was greatly increased by expressing the blood from the capillaries of the part operated upon, and this is done by pressure with a convex lens fitted into a ring attached to a handle. Above the lens, and set in the same ring, is a plain glass; between the glass is a space filled with circulating water, to keep the rays comfortably cool. By the use of suitable diaphragms the action is confined to a small space at a time. The treatments are repeated daily, and during them the nurse presses the lens so firmly upon the part as to completely empty the capillaries. As the period of treatment often extends over many weeks, or even months, the patience required is enormous; but for those who endure to the end the reward is usually great, as even the most inveterate and heretofore incurable cases result in a large percentage of cures. Besides the large operating room there are several small rooms, each with a single light, which are used for pay patients. Persons come for treatment from all over the world. Dr. Smith saw a number of patients who are practically well, and also photographs of the same cases at the time treatment was commenced. A large number of cases are of lupus. He asked the chief of clinic in what proportion of these there was an underlying tuberculous element, and was told in probably about 60 or 70 per cent. of the cases.

"Hydrophobia and That Sort of Thing."—This was the title of a paper by Dr. Reynold Webb Wilcox, in which he gave a report of the reputed cases of hydrophobia in the City of New York during 1902 and 1903, and also described a recent visit to the Pasteur Institute in Paris. In June last, he said, at a hearing before a committee of aldermen upon a proposed ordinance concerning the muzzling of dogs, the statement was made that in 1892 and up to that time in 1903 there had been ten deaths from hydrophobia. As the subject was one which commanded but little attention from the physician, he thought it opportune that it should be reinvestigated, so that some definite conclusion might be reached. Doubting the accuracy of the statement referred to, he requested from the Department of Health a list of those who were alleged to have died from hydrophobia during the time specified, with such other data as would enable him to prosecute his inquiry. This request having been courteously granted, he sent to each coroner or physician certifying to the death a letter containing a list of inquiries into the character and history of the case met with. Seven of the ten deaths were coroners' cases. In one of these the patient, a man thirty-two years old, was bitten in the right hand (wound cauterized), and symptoms developed after nine weeks. A post mortem was made, but the report of it is not on file. In another, the patient, a girl of nine years, who had been bitten some months previously, did not show any symptoms until just prior to death, when she developed convulsions, and died in them. There were no symptoms or history of hydrophobia and no evidence that the dog was mad. In a third case the patient, a woman sixty-two years old, was bitten in the right foot about three weeks previously. She took eighteen treatments (Pasteur), later was taken ill, and died after two days. The dog was shot on the same day he did the biting. In the other coroners' cases no evidence was obtainable. Of the three cases which were not coroners' cases, in two there was no conclusive evidence which he could obtain. The remaining case, in which the patient was placed under careful observation and in which the details were given, was the only one, Dr. Wilcox said, whose record needed analysis. The points militating against a diagnosis of hydrophobia were as follows: (1) The development of the symptoms twenty-four days after the bite is decidedly early; (2) leucocytosis can be accounted for as an ante-mortem phenomenon; (3) respiratory spasm is quite as common in tetanus as in various other conditions; (4) the temperature in tetanus, as here, usually remains low until just before death; (5) the mental symptoms are those usually found in tetanus; (6) inoculation experiments are not conclusive unless carried further than is stated. In the absence of more definite information, the diagnosis would more logically be tetanus than that stated. The most that can be claimed for these cases is that the diagnosis of hydrophobia is not proven. In some instances there is no evident reason why that diagnosis was assumed. Having given an account of a visit which he paid to the Pasteur Institute in Paris during the past summer, he gave the statistics of that institution since 1886. During 1902 1,106 persons were treated, of whom three died from hydrophobia. Inasmuch as in one of these the disease declared itself before the end of treatment, this case was excluded from both "persons treated" and "deaths." The deductions he derived from the table were: (1) Evidently the material used is prepared with great care; else in the presence of conditions favorable to sepsis (as observed by Dr. Wilcox at the Institute), more frequent indurations would result. (2) The patients are evidently cautiously selected, and the Institute has profited by the experience of the first three years, when the mortality was quite large.

Anyone reading the various papers on hydrophobia must have been impressed with their sameness, and a few years ago Dr. Wilcox discovered the common source of information or misinformation upon this subject. This was Van Swieten's Commentaries on Boerhaave, the Ziemssen of the eighteenth century, and in a chapter on "The Canine Madness" are to be found every fact and fancy, theory and superstition one is likely to need. He quoted a portion of this and then went on to say, "Having then found the source of information, and in one sense the forbear of the modern treatment of conditions of alleged sequence to dog-bite, may we not hope that less of assumption and more of logic shall enter into future discussions? A healthy skepticism as to the existence of hydrophobia as a nosological entity does not imply a negation of what has been accomplished by antitoxins or attenuated cultures (vaccines), for these have been demonstrated and their results proven. . . . However, the verdict deduced from the present inquisition, as it was from the one which I prosecuted in 1894, must be the Scotch one of "not proven."

A Mad Dog Scare.—Dr. Elmer Lee said he had visited the Pasteur Institute in Paris, as well as the great experimental institute at St. Petersburgh, and he could confirm all that Dr. Wilcox had said. Some years

ago there was a mad dog scare on Staten Island, and the dog, which was said to have bitten five persons, was kept under observation by the Society for the Prevention of Cruelty to Animals until it died, a few days afterward. An autopsy was made on it at the Loomis Laboratory by Dr. H. P. Loomis and Dr. Lee, and its stomach was found to be filled with curled hair from a cushion, which it had chewed in a barn in which it had taken refuge from a crowd of people who were pursuing it. In the heart there were 60 to 70 worms, which were some five to six inches long, and about the thickness of an old-fashioned metallic knitting-needle. Neither the brain nor the spinal cord presented any pathological condition. As a result of the examination they reported that there was present no post-mortem evidence whatever of the existence of rabies. Yet, in spite of this finding, the health authorities declared that the dog had died of rabies, and insisted that the persons bitten should undergo the Pasteur treatment. Personally, Dr. Lee had never seen a case of hydrophobia, and he should like to inquire if any member present had met with a single well-authenticated case.

The Existence of the Disease a Scientific Fact.—Dr. James D. Trask asked if he was to understand that there is no such thing as hydrophobia. He was surprised at the position which appeared to be assumed. He himself had seen and treated hydrophobia, and the existence of the disease as a scientific fact had been so conclusively demonstrated that he could not see how anyone could doubt it.

Hydrophobia at Least More Rare than Generally Supposed.—Dr. R. E. Van Gieson said that if he correctly understood the purport of the paper, the question had not been raised as to the existence of such a disease as hydrophobia. The author, however, did claim, and to a certain extent at least had proved, that hydrophobia does not occur as frequently as is commonly supposed to be the case. From his own experience he could say that he had seen persons treated by the Pasteur method who did not have hydrophobia. We do assert this much, he said, that hydrophobia is decidedly more rare than many would have us believe, and that the public has undoubtedly been misled in this matter. During a general practice extending now over nearly fifty years he himself had never seen a case. He had been called to see cases which were said to be hydrophobia, but which were really not the disease. Of two such cases, one was tetanus. The other was hysteria, and the patient got well. He had met with many instances, however, in which persons were bitten by dogs said to be rabid. He thought we might safely say that there is a disease given by the saliva of the lower animals, yet its symptoms were so irregular and its period of incubation so indefinite that much uncertainty existed regarding it.

Hydrophobia a Real Disease.—The President, Dr. Andrew H. Smith, related two cases he had seen at Bellevue Hospital, which were supposed to be rabies, and also spoke of the death within a period of three or four months, of 24 out of a flock of 48 sheep on a farm, which had been bitten by a rabid dog. It seemed to him that there were only two things which might be mistaken for hydrophobia—namely (1), tetanus, and (2) nervous exhaustion from fright (lyssophobia). As regards tetanus, he did not know of any case of the disease occurring where all signs of traumatism had disappeared for a considerable time. It was unfortunately the case that a dog which had bitten one or more persons was generally killed immediately, instead of being kept shut up under observation. In this way it was often impossible to say whether a dog had rabies or not, and those who had been bitten were thus apt to become the victims of their own terrors. He, therefore, considered it a crime to kill a dog under these considerations, and would have it made a State prison offense. He could not doubt that there was really such a disease as hydrophobia, and repeated instances of it were recorded in medical literature. Children had suffered from it who were too young to be affected with lyssophobia. Again, the inoculation from the medulla of animals and the reinoculation to the third or fourth series seemed to establish its entity on a scientific basis.

Dr. Wilcox, in closing the discussion, said he did not wish to be considered an iconoclast. He had not denied the existence of hydrophobia, and he did not wish any one to go away under that impression. All that he claimed was that as regards his investigation in 1894, when he collected 17 cases, and when he first visited the Pasteur Institute in Paris, and also his present investigation with 10 cases and a second visit to the Pasteur Institute, the verdict was that of "not proven." He himself, while working, in 1882, in a laboratory in Paris had been severely bitten in the finger by a rabid dog, and he bore the scar to this day. The wound had been treated only by ordinary methods, yet he had not developed hydrophobia; and he could give a number of similar instances. As to the presence of worms in the heart of the dog examined after death by Drs. Loomis and Lee, he believed this was quite a common occurrence with dogs. He would like to ask Dr. Ellis if this were not the case. (Dr. Ellis replied that it was.) Dr. Van Gieson, he thought, had stated the case very fairly. As to the inoculation of guinea-pigs and other animals, one series was not conclusive; for it had been shown that various powerful drugs, such as strychnine and atropine, were capable of producing symptoms identical with what is known as dumb rabies, the special manifestation of which was paralysis of the hind legs. To prove anything of scientific worth the inoculations must be carried through successive series. Personally he had seen two cases which had been diagnosed as hydrophobia; yet one of them, in a child, was shown by the autopsy to be a case of tuberculous meningitis, and the other, in which there were multiple abscesses, was undoubtedly one of septicemia. In his analysis of case No. 3 in the paper he had purposely omitted to mention the strongest point against its being an instance of hydrophobia in order to keep this in reserve in case anyone during the discussion should dispute the position which he had taken in regard to it. Van Gehuchten and Nélis maintained that in hydrophobia there was in the spinal and peripheral cervical ganglia, particularly the intervertebral ganglia and the plexiform ganglia of the pneumogastric, a destruction of the larger nerve cells, brought about by the migration of new cells from the capsule; these new cells invading the protoplasm and the nerve cells, and finally occupying the whole capsule. Ravenal and McCarthy claimed that these changes, with the clinical manifestations of hydrophobia, give a rapid and immediate means of diagnosis, but stated that their absence does not exclude hydrophobia. Delafield and Prudden denied that there are any characteristic changes in the disease. Finally, we come to Marinesco, who had demonstrated that the *Bacillus botulismus*, which is found in sausage poisoning, is capable of producing the same changes as those described by Van Gehuchten and Nélis as pathognomonic of hydrophobia. Furthermore, that the toxin developed is closely allied in its pathological results to that met with in diphtheria and tetanus. At present, therefore, Dr. Wilcox said, he thought it could be safely stated that there was no pathological anatomy of hydrophobia. How, then, he asked, could the disease be identified? As to the cases which he had studied, he could only say again that no other conclusion could be reached than that for these cases the finding must be "not proven."

DIET AND DRUGS IN NEPHRITIS.*

BY WILLIAM S. GORDON, M.D.,

OF RICHMOND, VA.;

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, UNIVERSITY COLLEGE OF MEDICINE, RICHMOND, VA.; VISITING PHYSICIAN TO VIRGINIA HOSPITAL, ETC.

ALTHOUGH the kidney is comparatively small in size, its blood supply is large and its function important. It has an excreting and probably an internal secreting work to perform. It is a long-suffering organ and has a heavy burden to bear. Its health depends, in a great measure, upon the normal metabolic and depurative work of the liver, upon the state of the genito-urinary tract below the upper opening of the ureter, upon the cutaneous circulation and vasomotor influences, and upon the absence of pressure and traumatism. Disease of the kidney may rapidly lead to destruction of life, or may persist for years without producing symptoms sufficiently marked to attract the patient's attention. On the other hand, the early restoration of function in some of the gravest cases of acute nephritis, and the slow but steady and resistless progress toward a fatal termination of most of the chronic cases impress upon the physician the importance of prompt diagnosis and treatment.

Inasmuch as the fundamental principle in the treatment of all diseased organs is to secure rest, and inasmuch as the work of the kidney is to eliminate certain ingredients of the blood, the retention of which would be injurious, it is essential in the management of nephritis not only to maintain a normal composition of the blood, but at times to so change the quality of the blood as to reduce its excretion products to a minimum. Syphilis, lead poisoning, and other infections or toxic conditions require, in addition, a specific or special treatment.

Since the quality and quantity of food and the use of alcoholic stimulants are acknowledged to be frequent and potent factors in the production of renal diseases, the matter of diet in nephritis is to be esteemed of prime importance. Dieting is not what the patient so often supposes it to be—starvation, but a regulation of food in such a manner as to rest the kidneys and, at the same time, adequately nourish the body. Nor should it be forgotten that a diseased kidney must be fed, and that no injury must be inflicted upon it by withholding what is required for its own vitality and the performance of any function at all. This truth necessitates a distinction in the treatment of acute and of chronic nephritis; in the former of which diseases complete abstinence from food for a while may be of great service, whereas in the other condition the blood must be enriched and the kidney nourished while its work is diminished.

Apart from the views of other observers, my own experience leads me to express the belief that gout and lithemia, in whatever manner produced, are responsible for a large number of cases of nephritis. Those of us who have studied our cases carefully and watched the effect of irritants in the blood or urine cannot escape the conviction that excessively acid urine, excess of solids, and especially the presence of excess of uric acid and calcium oxalate cannot fail, in the long run, to injure the delicate epithelium of the tubules and to stimulate the growth of connective tissue. In treating nephritis, therefore, it follows that a diet which promotes a normal reaction of the urine and prevents the formation of abnormal ingredients is clearly indicated.

Having attempted to lay down general dietetic principles, let us bestow some attention upon special articles of food. I recall a case of which a brother practitioner spoke to me, that of a young child suffering with acute nephritis, drinking a large amount of milk as an exclusive diet, but still losing a decided amount of albumin. I advised a diet of water and carbohydrates for several days, thus reducing to a minimum the amount of urea excreted. The result was prompt improvement. I have recently had under my care a little girl who had scarlet fever a year ago and who subsequently developed nephritis. Intermittent albuminuria persisted after the casts had disappeared. The milk diet adopted by the first physician who treated the case may have been serviceable in the acute stages, but the child was left anemic and the albuminuria was not relieved. I discontinued milk; allowed vegetables and fruits, chicken and eggs in moderation, administered iron, and sent the child to the mountains. At last accounts the albumin had disappeared and the patient was steadily improving. A third case is instructive—that of an elderly woman with a long-standing case of nephritis. I advised a diet mostly of milk. Constipation resulted and the albumin and casts increased. Complete flushing of the rectum and lower bowel caused a marked diminution of the albumin, and practically, a disappearance of the casts. These cases convey their own lessons, and teach that an exclusive milk diet, so often recommended for nephritis may do harm by being abused and furnishing too much urea, by causing constipation and absorption of toxins, by failing to supply the blood with sufficient nourishment, or by setting up lactic or butyric fermentation. The diet should be suited to the case, and a routine diet for all cases is unscientific and should be avoided.

*Read at the meeting of the Medical Society of Virginia, at Roanoke, Sept. 15, 16 and 17, 1903.

On the other hand, we are all familiar with the benefit derived in a large number of cases of nephritis from a diet composed wholly or largely of milk. Abstinence from alcohol, tea, coffee, and cocoa and a partial or complete reduction of sweets and acids, with the use of alkaline waters, rarely fail to produce prompt and beneficial results, especially in acute cases and in the first stages of the chronic cases. Haig claims that gout is not primarily due to excess of acids and sweets, but that these articles do harm by causing acid fermentation engrafted upon preexisting conditions due to excess of proteid food. However this may be, I am convinced that a large number of cases of nephritis, lithemia, gout, oxaluria, and other allied abnormal states, are not cured or held in abeyance merely by cutting off the main articles of food or drink which Haig enumerates as the causes of uricacidemia. It is true that nephritis, once established, changes the composition of the blood and, consequently, of the urine; but it is all the more true that abnormal blood leads to abnormal urine, and that abnormal urine leads to renal disease. My own rule is to so regulate the patient's diet as to maintain a normal urine; and so long as the urine is normal the kidney will, in the large majority of cases, be healthy or show marked improvement. Even secondary causes will under these circumstances be for the most part inoperative. So much for general principles. The careful practitioner will make special adaptations and note his results by repeated urinary examinations.

There is one point regarding nitrogenous food which ought to be emphasized, and that is that fowl, game, fish, and eggs should not be indulged in to excess because the patient has been prohibited the use of butcher's meat. There are cases in which all of the above-mentioned articles have to be cut out of the dietary. The injurious effects of eggs have been recently impressed upon me by the history of one of my cases, a young man who was markedly lithemic and for years had been the subject of an obstinate psoriasis. After months of treatment, large dietetic, he returned to me with samples of urine which showed a specific gravity of 1.036 and contained an abundant precipitate of calcium oxalate. The eggs which he acknowledged having freely eaten were prohibited, and in ten days the urine was in every respect normal.

Although I believe that hygienic measures are of paramount importance in the treatment of nephritis, I am not a skeptic on the subject of drugs. The more we study drugs and become familiar with their physiological action the more should we be convinced of their therapeutic value when intelligently employed. Their action is governed by certain laws which, in a measure, we are supposed to understand; and leaving out idiosyncrasies and unreliable preparations of medicinal agents, we may reasonably expect more or less success from an application of our therapeutics based upon the pathology and the correct diagnosis of the case in hand.

The value of diuretics in acute nephritis when urinary secretion has almost or entirely ceased is a contested point. Theoretically, they may be contra-indicated in many cases, and high authorities advise against them; but theories and the dictum of authorities often wane before facts. I can vividly recall two cases of scarlet fever occurring years ago in my father's family, and followed by severe nephritis and anasarca. The good old family doctor made an acetic extract of iron, so to speak, by dropping rusty nails into vinegar and drenching his patients with the potion. And I shall never forget how busy the attendants were kept carrying off the dropsy, and how rapidly the sick ones recovered. A year or two ago I was called in consultation to a man suffering from acute parenchymatous nephritis. The kidneys had apparently stopped working, and nothing but the profuse diaphoresis maintained by the attending physician saved the patient from fatal uremia. We concluded to give infusion of juniper and bitartrate of potassium. The result was magical; free diuresis set in, and the case rapidly went on to convalescence. Such happy results are often obtainable in chronic cases when the tubules become blocked. Irritating diuretics may do harm, but we are fortunate in possessing many agents which need not be mentioned but which are non-irritating and productive of the greatest benefit. In this connection, it is well to remember that an efficient cholagogue administered before the diuretic or in conjunction with it is a powerful auxiliary in the treatment. Free biliary secretion and open bowels are frequently sufficient to produce a prompt change for the better in the patient's condition.

The usefulness of diaphoretics, particularly in acute cases of nephritis, cannot be questioned. Such remedies as spirits of nitrous ether and solution of ammonium acetate, and others, have their place, but for emergencies pilocarpus stands at the head for efficacy and promptness. Depression, it is true, may accompany its action; but used with caution and in cases of uremia, with a strong and tense pulse, it is capable of changing the condition of the patient from one of imminent danger to one of comparative or complete safety.

I have already referred to the good effects of cholagogues. It is hardly necessary to mention the value of hydragogue cathartics and salines both in acute and chronic cases, and to invoke their aid when dropsy occurs, or when diuretics and diaphoretics are contra-indicated or fail in their action.

Nitroglycerin is oftentimes invaluable. In acute cases of nephritis with high pulse tension and diminished flow of urine its place cannot be easily supplied; while in chronic interstitial cases its influence upon the general and upon the renal circulation is equally pronounced. The tolerance of this drug by many patients is noteworthy. When normal pulse tension fails and the heart-chambers dilate, the resulting passive congestion is to be met with drugs which force the blood

through the kidney. It is here that digitalis is preeminent. In my own experience it has no equal, and there are few patients to whom it cannot in one form or another be safely and successfully administered. Its substitutes, however, may be necessary and are not to be underrated.

Although the measures used in chronic nephritis are more hygienic than medicinal, there are certain drugs, outside of those employed in complications, which serve a good purpose. Among these iron stands preeminent, especially when anemia has set in and the blood-vessels need to be nourished and strengthened. As to the particular preparation of this agent, I confess to a growing confidence in the old tincture of the chloride of our fathers and grandfathers. Much depends upon the dose and its combination with correctives and synergists. Bichloride of mercury, dilute hydrochloric acid and liquor of the chloride of arsenic are valuable auxiliaries, whose action, whether singly or in combination with iron, are oftentimes forcibly demonstrated in interstitial cases. In parenchymatous nephritis, with anemia, dropsy, and deficient urinary excretion, the time-honored Basham's mixture can hardly be dispensed with, as it is both a reliable hematinic and diuretic. It is encouraging to observe pale urine becoming normally colored under the use of iron, this effect being one which I always desire and endeavor to obtain, and which was very noticeable in one of the young children to which reference has been made. When the tincture fails, other preparations of iron can be used with advantage.

In anemic convulsions, no one doubts the efficacy of chloral hydrate and the bromides, but there may be those who would be disinclined to use morphine. For my own part, I do not hesitate to invoke its aid. It is the only drug which in certain cases will put the physician in command of the situation, and the patient is entitled to the relief or alleviation which it secures. I have never had reason to regret, on account of any injurious effects, the use of morphine when circumstances seemed to demand its employment. That it may do harm is undeniable, but unpleasant effects can be prevented by not giving too large a dose. Veratrum viride is a remedy with which my experience is limited, although its virtues as a reducer of pulse tension and an internal bleeder are well established. In acute inflammatory conditions, with a strong pulse, the good results obtained from aconite must not be forgotten.

For the debility which, sooner or later, appears in all cases of subacute or chronic nephritis, recourse must be had to stimulation. The selection of the agent for this purpose requires discrimination. On account of the physiological relation of urea to ammonia, it is questionable whether the salts of ammonium may not, if too long continued, increase the production of urea, a result which is far from desirable when the secreting epithelium of the tubules is partly or wholly destroyed. Under these conditions a fatal termination is not far off; nitrogenous food itself makes the patient worse; and any drug which causes tissue waste or increased formation of urea in the liver is, if possible, to be avoided. Alcohol, so often the first cause of nephritis, may be beneficial, especially in elderly people who are the subjects of gradual degeneration of the kidney. It is best to give it with food. In other cases, however, its regular use as a stimulant cannot fail to react upon the system and intensify the symptoms which it may temporarily appear to relieve. Strychnine may be contra-indicated in excitable states of the nervous centers, but in such conditions the pulse is usually tense or strong, and the drug would not be considered. Many are the times when it can be given with propriety and marked benefit. When the heart fails and the pulse grows soft, thin and frequent, it is a powerful ally of digitalis. Taken all in all it is the best remedy in our possession for weakness and exhaustion of the nervous system, while its combination with the hypophosphites will sometimes produce results unattainable by either drug alone.

In conclusion, it is needless to add that it has not been my purpose to treat the subject exhaustively, nor to discuss fully specific articles of food and specific drugs. On the contrary, my aim has been to call attention to the underlying principles which should be observed in treating nephritis with diet regulation and medicinal agents. The leading drugs have been mentioned in order to illustrate principles, and, with the same idea in view, reference has been made to certain important articles of food. If what has been written will stimulate to a deeper study of the physiological action of drugs and of the metabolism of food products in the body, and lead to a renouncement of that skepticism on the subject of medicinal therapeutics which is growing too common in our ranks, I shall be abundantly rewarded for the privilege of reading this paper.

MASTOID DISEASE AND CEREBELLAR ABSCESS.

BY SEYMOUR OPPENHEIMER, M.D.,
OF NEW YORK.

The importance of encephalic pus collections in their relation to the diseases of the temporal bone, in which purulent inflammatory changes play an essential part, can only be estimated by the amount of destruction wrought in the brain tissue and adjacent structures and by the lethal issue resulting in the absence of prompt recognition and surgical relief. While various portions of the brain may be the seat of abscess formation, the temporosphenoidal lobe and cerebellum concern the otologist more than any other portions, as these areas are the most frequent site of secondary infection from the temporal bone. Cerebellar abscesses as far as their primary origin is concerned, may be classed into two groups, those due to infection by way of the labyrinth, through the petrous portion of the temporal bone and a second class in which the infection is derived from the mastoid process. The latter is the form which I desired to consider here.

The location of the pus collection in the cerebellum when derived from the original mastoid focus, is practically more or less constant in the anterior portion of the lateral lobe and on the same side as the area of bone necrosis, although in rare instances, multiple, discrete abscesses have been found on autopsy. Moos records a singular case in which the cerebellar abscess was on the opposite side to the diseased ear and was also associated with a cerebral abscess on the same side as the ear affected. The source of infection if far back in the mastoid process, will produce the brain lesion in the posterior part of the cerebellum, the direction in which the ear disease may be propagated varying as shown by Pitt, with the position of the sulcus for the lateral sinus.

While the groove varies considerably in different cases, in some temporal bones it is found well forward and in very intimate relation with the mastoid cells, so that the presence of a necrotic area in this vicinity, would greatly aid in facilitating the spread of the infection backward toward the cerebellum. For should this slight barrier break through and an extension of the purulent process take place through the inner wall with a circumscribed meningeal infection, this portion of the encephalon will inevitably be the seat of the pus collection. The sigmoid groove thus plays a prominent part in the conveyance of the infection, although the osseous lesion as regards its primary inception is less directly in relation with the abscess cavity than is usually the case with cerebral abscesses.

The thickness of the inner mastoid wall also acts as a restraining factor, particularly in children, the rare occurrence of cerebellar abscess in the very young from this locality, depending as shown by Gruber, upon the fact that the bony material intervening between the mastoid antrum and the cranial cavity, exists in relatively larger amounts in early life, than at a later period. But at any age, should this intervening layer of bone undergo destructive changes as the result of a mastoiditis and the suppurating process convert the sinus into an abscess cavity, the chances are largely in favor of a subsequent cerebellar abscess, provided the patient does not succumb to the sinus phlebitis or infective meningitis. The brain abscess however, does not in all cases necessarily follow the mastoiditis directly, but may arise from an infective sinus thrombosis or an epidural abscess.

The large proportion of the cases of this class not being dependent upon an acute ear affection, as cerebellar abscess from this cause is very rare, but rather from an exacerbation of a chronic or latent focus of infection in the mastoid cells, which has been incited to renewed activity by some recent irritation. Such a case being reported by Kirkland in a boy of sixteen years, where the aural trouble has existed for three years. There was intense pain in the left ear, the temperature was 103° F., the mastoid was swollen and when the latter was opened it was found to contain but a few drops of pus. Severe occipital pain, left optic neuritis, vomiting, giddines and drowsiness with a normal temperature and pulse then ensued and the skull was trephined one inch above the suprameatal wall with a negative result. On the following day the skull was again trephined over the cerebellum and a half dram of foul pus was evacuated, with the ultimate disappearance of the bad symptoms.

In other cases the inner mastoid wall may remain perfectly intact and the infection will travel through the small channels in the bone by way of the minute veins running from the surface of the cerebellum to the lateral sinus and from this location to the mastoid interior. The following case in which the infection was traced directly from the mastoid cells, resulted in a successful termination after operation:

L. G., male, aged thirty years; has had otorrhea of the right side for ten years, but no serious symptoms were complained of until one week before he was first seen, when giddiness and pain over the mastoid region developed. The mastoid was swollen and tender, with bulging of the wall into the canal and usual signs of a chronic otitis were present with a perforation in the posterior inferior segment of the drum membrane. He also complained of a gradual loss of weight and there was facial palsy on the same side as the mastoid disease. Anorexia, constipation and foul breath were also present, with beginning optic neuritis. Vertigo was the most prominent symptom, while nausea and vomiting were also occasionally present. Intense pain was complained of over the occipital region on the right side, with sluggish reaction to light of the dilated right pupil, and the temperature was 97.2° F., while the pulse varied between 60 and 70. Physical weakness was extreme, the gait was staggering, there was weakness of the right arm, exaggerated knee-jerk and the patient lay on the left side.

Cerebellar abscess following mastoid disease was diagnosticated and immediate operation was advised and consented to by the patient. Under ether anesthesia and with the usual aseptic precautions, the mastoid operation was first performed and considerable greenish pus and necrosed tissue was found occupying the mastoid cells, while a minute sinus with a corresponding small area of necrosis, led into the sigmoid groove. This was removed and the sinus was found to be somewhat discolored but otherwise healthy, while the dura was bulging into the wound. The brain membranes were opened and a grooved canula was plunged into the cerebellum, when about half an ounce of fetid pus was evacuated. Introduction of the encephaloscope showed a firm, resisting, limiting membrane. The abscess cavity and mastoid wounds were gently washed out with a 1:5,000 bichlorid solution and a gauze drain inserted. The temperature ran an erratic course for several days, but at the expiration of a week all of the severe symptoms had disappeared. The abscess cavity continued to discharge for two weeks when it ceased

and the patient rapidly made an uninterrupted recovery.

The frequency of cerebellar abscess, as compared with the intracranial complications of mastoid disease, is but small; Barker believing, from his experience, that less than a tenth part of the ordinary complications of aural disease consists of this form of pus collections. While Gradenigo, in a study of 68 cases of mastoiditis, found endocranial complications in 12 and of these but two were cerebellar abscesses. As regards the proportion of cerebellar to cerebral abscesses one may safely say that of all encephalic pus collections of otitic origin, at least 25 per cent. are located in the cerebellum and that the majority of these are in the anterior surface of this portion of the brain, in immediate proximity to the sigmoid groove. Körner, in 100 cases of brain abscess, found the cerebellum alone involved in 32, while in six cases both cerebrum and cerebellum contained a purulent focus. He found twice as many in males as in females and also agreed with the majority of observers that they were more common on the right side. Allport, in 169 cases, found 31 in the cerebellum; Jansen, in 16 otitic brain abscesses found 9 in this locality, a quite unusual experience; while Picque and Ferrier, in 119 instances, found 24 in the cerebellum, 4 in both this locality and the cerebrum and 1 in the peduncle. Barr, in 76 cases, found abscesses 13 times in the cerebellum. In children as before mentioned, it is quite rare in this location, although one may be safe in estimating the percentage here as compared with all encephalic abscesses, at from 15 to 20; the greater development of the pneumatic spaces in the adult, increasing the predisposition to cerebellar abscess as a complication of mastoiditis.

The symptom-complex of cerebellar abscess, while irregular and at times far from characteristic of the lesion present, may in some cases allow of the grouping of the symptoms, so that four stages of the process may be fairly well distinguished. The first commencing with the symptoms signifying the extension of the infection from the mastoid process to the cerebellum and classified as the initial onset of the local infection. This is followed in the majority of cases by an arbitrary second stage characterized by mild discomfort in which the disease remains latent and usually is not recognized. The third stage supervenes at a longer or shorter period of time and the symptom group of this period is characteristic of a severe otitic intracranial infection, sometimes with symptoms pointing to a localized cerebellar abscess, while more frequently, the pus collection is only localized after the parts have been explored by operative procedure. When, however, this stage is not recognized and the intracranial condition is allowed to continue without surgical relief, the fourth or terminal stage of the disease is an essential sequence, manifested by exhaustion, coma and the gradual death of the patient, or by sudden death from rupture of the abscess into some vital portion of the brain axis.

The initial or formative stage of cerebellar abscess, presents no definite signs as regards the localization of the disease, but the usual symptoms present at this time are those of an acute extension of the mastoid suppuration to the intracranial contents and are usually more characteristic of a sinus thrombosis or a localized area of meningitis, than of a cerebellar affection. A temperature that is already high as a result of the preexisting mastoiditis, becomes a degree or more so, the pain over the mastoid region becomes more severe and may extend back over the occipital region, while vomiting may occur once or twice and then disapper or the symptoms may increase in severity and operative interference be indicated on account of the associated morbid pathology. In a large majority of the reported cases, however, the onset of the intracranial complication, if acute, as here described, was unnoticed, or the infection was gradual, probably covering a period of many weeks or months and passing into the second or latent stage, with a subsidence of any of the acute symptoms that might have been present.

Even more so than in the first stage are the symptoms at this time indefinite and often not of sufficient prominence to attract attention to the aural disease as the cause of the gradual failing in health, with frequent periods of intense headache, varying anorexia, more or less depressed mental condition and fairly well marked aprosexia. If a thorough examination were made at this time, an intracranial lesion at least would be suspected, but unfortunately such is not the case and if the patient seeks advice at all, he is usually treated for some vague general condition and an opportunity is lost, which cannot be regained. Such a case came under my indirect observation, several years ago, in a young man of twenty years. He had been in previous good health except for a suppurating right otitis which discharged at irregular intervals, but not enough to cause him any concern. Then the mastoid became painful and swollen, but under local medical treatment by his family physician, soon disappeared and nothing further was thought of it. It was noticed, however, that he gradually began to lose weight, to complain of frequent occipital headache and to have attacks of nausea and vomiting. His mental condition became dull and he would deliberate in answering even a simple question for several minutes before he gave a reply. This continued for several months, during which time he was taking medicine for a supposed gastritis and finally the symptoms enumerated became so marked, that he was referred to a hospital for a further study of his condition. Seventy-two hours later he died from a large cerebellar abscess which had ruptured into the ventricle, as shown by autopsy.

The third stage like that of the others, of course presents no fixed boundary lines, the transition from one to the other being gradual and usually not recognizable, but for purposes of study, these cases admit of some differentiation of symptom

groups with their pathologic stages. At this time the full complement of symptoms have become well developed, and, according to v. Bergmann, can again be profitably subdivided into three groups: the general symptoms; those due to pressure and local pathologic changes; and the localizing symptoms.

Of the general symptoms, physical weakness usually becomes more pronounced as the abscess develops and the muscular asthenia is especially marked on the same side as the pus collection, being chiefly confined to the arm. The muscular weakness may also be evident by the conjugate deviation of the eyes toward the unaffected side, from asthenia of the ocular muscles and not from direct special nerve involvement. This muscular atony, whether local or general, develops most insidiously and may be the first symptom noted; its importance in connection with other symptoms being considerable as indicative of a brain abscess. A gradual impairment of the appetite, sometimes amounting to complete anorexia, may also be present, but in conjunction with a coated tongue and a peculiar yellow color of the skin, is indicative only, like the majority of the symptoms, of a septic intracranial condition and like those present in many grave diseases, is dependent upon the gradual absorption of septic material and its resultant action on the general organism.

The symptoms due to pressure and local pathological changes vary in almost every individual case, but the presence of headache is fairly constant in all, usually being the earliest and most conspicuous symptom. It is occipital in location and while very intense, is increased by pressure or percussion especially over the region of the abscess. Generally constant, at times it is not so severe, but again becomes almost unbearable. Rarely it may involve the frontal region and then of course, greatly interferes with the recognition of the pus collection, but as a rule it is situated in the former position, being duller in character and more limited in extent than that due to other intracranial lesions. Sometimes it may be the only practical symptom of importance for a time, as in a case reported by Heiman, of a man of twenty-four years, with sudden onset of headache increasing in intensity, following the suppression of an aural discharge. No characteristic symptoms were present but in addition to the headache he had some fever and pain in the ear. Death occurred within twenty-four hours after the beginning of the headache and the autopsy showed a ruptured cerebellar abscess in the process vermicularis.

Nausea and vomiting are almost always present but are not necessarily characteristic of cerebellar abscess. In connection with other symptoms and especially with unsteadiness in gait, vomiting may assume more or less of a characteristic aspect and then depends to a great extent on pressure exerted upon the middle lobe of the cerebellum. In connection with dizziness, vomiting has also been of great value in making a diagnosis as shown by Green and Crombie. Vertigo is present in nearly all cases and may be associated with a loss of the sense of equilibrium, the patient presenting a staggering gait. Or in the sitting posture the head may fall forward, then turn towards the unaffected side and continue to move with pendulum-like oscillations, this condition is extremely rare however and in such cases, the vertigo is a prominent symptom, being constantly kept up by the head movements.

The mental functions are usually disturbed and at first somnolence is common, but may be in isolated instances replaced by a condition of sleeplessness, this being the only symptom for which the patient seeks advice. The mental state may often furnish valuable information especially when the patient is irritable at times, while at others he may be inattentive or the hebetude as the disease advances, gradually giving way to stupor. Sluggish cerebration may be quite noticeable and the peculiar condition may exist in which, if a simple question be asked the patient, he will not appear to have heard it and no notice will be taken for a time, then in a few minutes he will begin to answer slowly and deliberately, dwelling carefully on each word as it were, but the final answer will be correct.

The temperature at this stage is of much value as a symptom of brain abscess, but gives no information as regards the site of the pus collection. Oscillations of the temperature are as a rule not present, and it remains fairly constant at or near 99° F. after the initial rise due to the primary extension of the disease to the cerebellum. Very often it is normal or subnormal and when the latter is continuous in connection with an aural lesion, the presence of intracranial abscess may be fairly well assumed. In some cases the diagnosis in great part will hinge on this symptom, a case in point being that seen by Morris, where the low temperature in connection with a subnormal pulse rate, led to the diagnosis of a brain abscess, but precise localization was impossible. The autopsy showing a cerebellar abscess on the same side as the diseased ear. The pulse is also slow, regular and of fair volume and remains unchanged in uncomplicated cases, but it may be normal and occasionally become intermittent. An instructive case in this connection being seen by Schwartze, in which the prominent symptoms were intense, intermittent pain in the occiput, nausea, vomiting, subnormal temperature, irregular pupils and a rapid pulse of 100 to 150. No operation was performed, as the rapid pulse was considered incompatible with a cerebellar abscess, but the necropsy showed an abscess in the right cerebellar hemisphere, with circumscribed leptomeningitis and pachymeningitis interna and the cause of the pulse rate was readily explained by the finding of a chronic endocarditis. Respiration is usually regular, but often slower and more shallow than normal.

Of the minor symptoms of this class, which are variable and may or may not be present in the given case, cervical contracture is one of the most

frequent, the muscles of this region may also present varying degrees of rigidity and from the same cause, clenching of the teeth may occur infrequently. The tongue may be protruded toward the unaffected side, making the speech slow and indistinct, if it be swollen. Rigors occur infrequently, the bowels are constipated and the knee-jerk may be increased on the same side as the brain lesion. Walker reporting a successful case following operation, in which the only characteristic symptom was the increased knee-jerk.

The localizing symptoms are of little value in this affection, although Burnett states that double optic neuritis is likely to be present, because the abscess readily interferes with the circulation of the cavernous sinuses and the ophthalmic veins. Very often this may be the only positive symptom, but again the eye-grounds may remain normal even in fatal cases, as has been shown by Woodward. Hansberg believes that localization of a cerebellar abscess is almost impossible from focal symptoms, but he considers bilateral choked disks as the only sure sign, while Gradenigo states that lesions of the optic papillæ are observed in about one-half of these endocranial complications and they should be carefully sought for, as they are frequently the first and only indication of intracranial involvement. He further states that the papillitis affords no information in regard to the location of the lesion.

Nystagmus and paralysis of the sixth nerve may point to a lesion in this locality, the paralysis of the abducens producing strabismus, as in the cases seen by Barling, one of which had this nerve affected, while both presented horizontal nystagmus. The pupils may vary in size, the more dilated being on the side of the abscess and there may be inability to close the eyelids, with facial paralysis on the same side; this and paralysis of the oculomotor nerve may be the only localizing symptoms. Should facial paralysis occur it will probably be due to pressure of the abscess on the nerve in the pons, but as is frequently the case, a large abscess may be present and yet produce no localizing symptoms. Cerebellar ataxia and vertigo are usually due to lesions of the worm, while if the medulla be affected to a point low enough, the varied paralyses may be unilateral and on the same side as the abscess, if, however, the pons be involved more on the side of the abscess, the paralysis will be apparent on the opposite side. Macewen has well said that in all cases the symptoms of cerebellar abscess "depend upon the level of the pressure," but one may conclude that local symptoms are not usually present unless the abscess develops to the point of invading the middle lobe or the peduncle, when the so-called cerebellar ataxia develops.

The terminal stage is one of gradual death from exhaustion and coma; or sudden, depending upon the direction in which the abscess ruptures. When the pus breaks into the ventricle, the condition changes at once, the temperature rises suddenly to 103° or 105° F., the pulse becomes rapid, respirations are frequent, while there are muscular twitchings, convulsions, coma and death. When, however, the abscess ruptures upon the free surface, a secondary, inflammatory reaction ensues leading to acute purulent leptomeningitis. The temperature becomes high and the pulse rapid and the symptoms of meningitis are fulminating, ending rapidly in the death of the patient.

The complex of symptoms, as seen in cerebellar abscess, is well exemplified in a study made by Green of four cases, in which headache as a prominent symptom was bilateral in two, frontal in one and vertical in one. No occipital headache being present in any of the cases. Paralysis of the abducens occurred in two, of which one was bilateral and one unilateral and on the opposite side from the ear disease. Optic neuritis was seen in only one case. One had general septicemia, while in the others, fever was not apparent at any time. Nystagmus on looking away from the diseased ear was present in but a single case. The abscesses were in the anterior lower portion of the cerebellum on the same side as the ear disease and in all the cases an accurate diagnosis before the operation was impossible. Leucocytosis was found in those in which the examination was made for this phase, but as the author well states, it is found in nearly 80 per cent. of uncomplicated tympanic suppurations and therefore possesses no diagnostic value in this connection.

Hammond, in five cases, based his diagnosis upon the following complex of symptoms which he regards as characteristic, being confirmed by operation or autopsy. Present or previous suppuration in the sinuses adjacent to the brain, rapid loss of flesh and strength, rapid pulse and high temperature for the first seventy-two hours, followed by a decline in the temperature and an increase in the heart action. There is also pronounced flexure of the extremities, progressive dilatation without fixation of the pupils, semi-unconsciousness with uncontrollable restlessness and a peculiar indisposition to obey any requests that may be made. Glycosuria, slow respiration and a tendency to go toward one side are present, while there is also a swinging of the hands toward one side, with an entire absence of paralysis.

The two groups show very well the multiplicity and confusion of symptoms, and it is only by the careful study of the individual case from all sides, that a diagnosis can be made and the value of the symptoms even approximately estimated.

The pathologic changes in the primary bone infection consist of an area of necrosis at the point where the plate of bone separating the sigmoid sinus from the mastoid cells is extremely thin, so that erosion, as shown by Bacon, is apt to be at this point. The bone becomes discolored, softened and granulation tissue develops, while a collection of pus is found either between the sinus and bone, or behind the sinus in the direction of the occipital bone and by means of the small veins or arteries the infection is carried into the cerebellum. Or, as before mentioned, there is a direct contact between the sinus and the cerebellum, by means of the dura. This phase of

the necrosis, as seen in the sigmoid groove, may be of great diagnostic value, as indicating the course of the infection toward the cerebellar region, when an exploratory operation is performed in the absence of definite localizing symptoms.

Wherever the abscess is situated, its development is usually accompanied by that of other intracranial complications, as sinus phlebitis or a small limited area of meningitis, and it is usually single, but they may be multiple and involve the cortex or deeper regions on one of both sides. Even when single, as is more frequent here than in cerebral abscesses, a smaller pus collection may be found in close conjunction with it, or an abscess here may coexist with one in the cerebrum. As the majority of abscesses in this location are chronic in character, they become capsulated by a definite lining membrane, varying in thickness from 1 to 5 mm. and although this acts as a barrier to the further spread of the infection, yet in some instances, this conservative barrier is absent, the abscess being surrounded only by a zone of softened brain substance. Whether encapsulated or not, there is always present the tendency toward greater growth and the size is extremely variable, some containing but a few drops of pus, while from others, three or four ounces may be evacuated, a case in point being seen by Woodward, in which the entire white matter of the left hemisphere of the cerebellum had broken down into an abscess cavity. The pus found in the abscess does not usually differ from that found at the original focus of infection and it may be thick and yellow, or thin, greenish and offensive, at the same time containing particles of broken down cerebellar tissue.

The following case of cerebellar abscess was seen in consultation a short time ago and well shows the difficulty of diagnosis:

M. J., male, age fourteen years, presented the following history. The right ear had been discharging for two years following an attack of la grippe. He had been under treatment more or less constantly for the otitis, with the cessation of the discharge at times, but with its recurrence after attacks of coryza. He has lately complained of occasional dull pain over the mastoid and has become irritable, with, in addition, a considerable loss of weight. The discharge at times would become excessive in amount and the pain in the head would then become greatly aggravated. At the time I first saw him, the pain and restlessness were marked, the mastoid was not swollen, but pressure produced flinching. There was a small perforation low down in the drum, with considerable purulent discharge and a macerated appearance of the canal, but no definite areas of redness or swelling. The temperature was 98.6° F., the pulse 74 and the respiration normal. The middle ear was cleansed and drained with a small gauze wick, an ice bag was placed over the mastoid and sedatives were given internally. He only slept a few minutes at a time during that night and on the following day the symptoms had increased, although the appearance of the parts remained apparently unaltered. No other symptoms than those mentioned were present and the eye-grounds remained unchanged.

Operation was then advised and under ether anesthesia, the mastoid was opened. The cortex was exceedingly dense and no pus was found until the antrum was reached, which contained a few drops of purulent matter. Free communication was established with the tympanic cavity, a small patch of necrosis was removed, the wound was dressed in the usual manner and an improvement in his condition became noticeable in a few hours, the headache ceased and he had a good night's rest. This improvement continued for a week, when he became restless, was constantly annoyed by trivial matters and his temperature, which had been normal, fell to 97.2° F., while the pulse was 64. I then saw him again and found him very irritable, the right pupil was dilated, he complained of the light and the optic papilla was slightly swollen, while he was losing flesh and strength rapidly. The mastoid wound was to all intents normal, but was redressed, and when I saw him on the following day, he was semi-conscious, there was a slight stiffness of the nucha and a diagnosis of brain abscess was made, supposedly located in the cerebellum.

On account of his grave condition, it was deemed best to immediately explore the cerebellum and delay opening the mastoid wound, as it seemed perfectly healthy. A trephine opening was then made in the usual situation over the cerebellar region and when the button of bone was removed the dura was seen to be somewhat inflamed. A small incision was made in the dura and a hollow needle inserted into the lobe of the cerebellum, when, after encountering a dense encapsulating wall, five drams of pus were evacuated. The abscess cavity was washed out, drained and the usual dressings applied. The patient seemed to rally well from the operation, but died twenty-four hours later from apparent asthenia. A partial autopsy only was allowed, but it showed that the sinus was involved and that the infection had reached the cerebellum through the small veins, from a minute purulent and necrotic focus well back on the inner mastoid wall.

Of all the intracranial complications resulting from mastoiditis or other suppurative affections of the organ of hearing, cerebellar abscess is undoubtedly the most difficult to localize. And, as has been shown by Gradenigo, neither optic neuritis, lateral nystagmus, titubation, vertigo, nor rigidity of the nucha are special symptoms. In many cases the location of the lesions one finds in the course of a mastoid operation with symptoms of endocranial abscess such as caries of the sigmoid groove, with thrombosis of the sinus, will be the only indication that the pus collection is probably situated in the cerebellum. In the cases where a diagnosis is made in advance of operation, it is only by the careful study of the complete symptom-complex, as it is almost impossible to do so from focal symptoms alone, and when recognized early it is more often by a process of ex-

clusion, rather than by any definite signs or symptoms.

The difficulties of recognition are also often enhanced by the frequent presence of complicating factors such as pyemia, sinus thrombosis or meningitis. In sinus thrombosis, rigors, high temperature and increased heart action, are almost always present, while in leptomeningitis there is high temperature, rapid pulse and marked irritability of the special senses as predominating symptoms. Heiman believes that if due consideration be given to all the symptoms, an accurate diagnosis can be made in three-fourths of the cases, and while it is not of much value to place reliance upon single symptoms, yet in many cases one can be fairly sure of the presence of a cerebellar abscess, when certain groups of symptoms are studied in relation with one another. Cerebellar abscess may materially lower the temperature in the presence of a complicating sinus thrombosis and when a case of suspected intracranial complication is seen, this factor should be thought of. Achard and Bellanger believe that paralysis of the arm of the affected side with muscular weakness of the legs, exaggerated patellar reflex on the same side and conjugate deviation of the eyeballs toward the unaffected side, are especially indicative of this condition. And, as has been suggested by Church, in this connection, the X-rays may be of service here, the same as they have been of use in cerebellar tumors, but no cases have been recorded as yet of their value in this field.

In the differential diagnosis between temporosphenoidal and cerebellar abscesses, the usual error is to mistake the latter for the former, but the localizing symptoms of cerebral abscess are usually present sooner or later, and if a decision cannot be made, an exploratory operation will be of great help. Examination of the visual field may yield valuable information, but choked disk alone simply indicates an intracranial lesion and is not characteristic of an abscess in this locality and does not explain the nature of the lesion. Grant reports two interesting cases, in one the diagnosis was rendered more difficult by the presence of labyrinthine symptoms, while in the other, both ears were affected and rigors were very prominent, due to other complicating factors. Disease of the labyrinth and semicircular canals may account for some of the symptoms as in a case reported by Bacon, with slow pulse, vertigo, vomiting, deafness, headache, etc. In this case a cerebellar abscess was supposed to be present, but the operation showed caries of the semicircular canals. In Menière's syndrome, the headache is neither so violent, persistent, nor localized, and while in cerebellar abscess the somnolence and stupor may increase as the diseases progresses this is not the case in the former.

Subnormal temperature is often present after influenza or other depressing diseases, but it is usually of short duration and not continuous like that of cerebellar abscess, while rapid emaciation may be due to the same causes, but when, in addition, the temperature is low, and there is constipation, sluggish mental action and localized pains in the head, the diagnosis is strongly in favor of the cerebellar lesion. The cerebellar gait, so-called, while of strong presumptive evidence, may be due to irritation of the auditory nerve or semicircular canals, as has been shown by Starr, and a similar syndrome be produced by defective aural drainage, without the presence of an abscess at all, the symptoms being relieved after the defective drainage has been rectified. Tumors of the cerebellum, such as glioma, tuberculous, etc., may produce symptoms very similar to abscess, but the differentiation can usually be made by the presence of other factors resulting from pressure on surrounding parts.

The early stage of the abscess formation, corresponding to the initial infection from the mastoid, may last only for a day or two, or a week at the utmost, while after these acute, primary symptoms have subsided, it may remain latent for a number of years, being incited to renewed activity by the development of a new inflammation of the original focus of infection. One, and possibly two, extraordinary cases have been reported, in which the abscess spontaneously evacuated through a carious opening in the sigmoid groove, but such a result seems hardly credible and one should never, for a moment, anticipate such a termination. The usual tendency of the abscess, if not operated on, is to cause death by pressure edema of the surrounding parts, or to perforate externally with resulting meningitis; or internally, into the fourth ventricle, with immediate death from cardiac and respiratory paralysis.

While the patient will invariably die without operation, yet the success obtained in this field has been so promising that one is justified in operating as soon as the diagnosis is made, but in some cases one may wait a short time for the development of any symptoms more closely indicating the location of the abscess.

As the only treatment for cerebellar abscess is surgical, the primary focus in the mastoid should, as a rule, first be exposed and the tract of the infection traced, if possible, to its results further back. Bergman states that with a history of ear disease, persistent sleeplessness and a continuous temperature of 99° F., one is justified in opening the cranium, but the otologist may wait for localizing symptoms or until a condition of hebetude is well pronounced, before interfering. The advantages of delay are, that the location of the abscess may be more apparent later on, while the danger to the patient is not materially increased. As pointed out by Bramwell, in cases where the diagnosis is uncertain, the operation adds but little to the risk.

It is always advisable, after cleaning out the mastoid, to expose the sigmoid sinus, while to get at the inner surface of the mastoid, the posterior portion of the bone can be removed until the dura is fully exposed for at least 2 cm. behind the lateral sinus; exploration can then be made in the cerebellum in any direction to the depth of 3½ cm. inside of the lateral sinus. In exploring, in

the absence of a precise diagnosis and in the presence of grave symptoms, it is best not to incise the dura, as the hernia which sometimes follows is a serious complication and should not be incurred, unless in the presence of immediate danger or when the diagnosis is probable. Intervention should, at times, be limited to exploratory puncture and aspiration. Gradenigo in one case by this method, aspirated fragments of cerebellar tissue and excluded a deep abscess, without in any way injuring the patient.

The general routine of procedure in these cases has been well mapped out by Pritchard, and he advises to first open and explore the mastoid cells and antrum. Failing here to find sufficient disease to account for all the symptoms, open the cranium in the groove for the lateral sinus and so obtain access to both the middle and posterior fossa. Then examine the lateral sinus and search for both extra- and intra-dural abscesses. Treat the sinus as indicated by any pathological changes present, and if the sinus is not thrombosed, explore the cerebral substance above and the cerebellum below the level of the horizontal groove of the lateral sinus. If there is an urgent need of operation and the diagnosis is fairly established, the brain cavity may first be opened over the supposed site of the abscess and the mastoid operation performed later. But the aural lesions should receive attention immediately thereafter, or, if the condition of the patient is such that this is impossible, the mastoid should be operated upon subsequently. But it should always be remembered that the aural lesion is the original cause of the brain disease.

When the mastoid is sclerosed or eburnated, or for any reason that will make the ordinary operation inadvisable, the skull may be opened from 5 to 7 cm. back from the edge of the osseous meatus, just below the superior curved line of the occipital bone and on a line drawn from the inferior osseous edge of the orbit to the occipital protuberance. The technic for opening the skull here is the same as in other situations, but the pus in a cerebellar abscess is apt to be so thick that it will frequently not pass through the ordinary needle, and after the dural flap has been raised, it is best to use a large grooved exploring needle. If pus be found, the cerebellum is freely incised with a probe-pointed bistoury and the abscess cavity is evacuated and a proper drain inserted.

45 East Sixtieth Street.

A DISCUSSION OF SOME COMMON FORMS OF LIVER DISTURBANCES.*

BY A. P. STONER, M.D.,
OF DES MOINES, IOWA.

The liver is not only the largest, but from the standpoint of amount and variety of work, it is easily the most important gland of the body. The workings of the delicate and complicated mechanism of the liver cell, to a large degree, still defies the acutest and most refined observations.

It is the great refinery and safeguard of the organism against unassimilable and poisonous substances, where the detritus of metabolism from all the tissues of the body is discharged and prepared for excretion; the laboratory wherein the

* Read before the Des Moines Pathological Society, April, 1903.

blood is purified, and the worn out hemoglobin molecule, after being robbed of its iron, is cast out, with other débris, as bile and urinary pigments.

It is one of the principal storage rooms of the body, wherein the carbohydrates are transformed and shelved, to be used in the interim of digestion.

While the general pathology of the liver has been well worked out, much of the functional and clinical pathology yet remains within the chrysalis of ignorance. As only the commoner forms of liver disturbances are to be discussed in this connection, mention will only be made of such conditions as are likely to be met by the practitioner in temperate climates.

Hyperemia.—"Congestion of the liver" is a term that has so long been wielded by ignorant pretenders in the practice of medicine that one might be excused in questioning its existence as a real pathological entity.

A noticeable degree of hyperemia of the liver is occasioned by the ingestion of an ordinary meal. Highly spiced foods and alcoholic beverages produce excessive hyperemia. This engorgement, however, soon passes away, unless the dissipation be long continued, in which case structural changes may ensue. More or less congestion of the liver may accompany valvular heart disease.

Two conditions, said by many authorities to produce hyperemia of the liver, viz., sudden suppression of the menses and hemorrhoidal bleeding, both of which probably have very little effect upon the organ. A few days before the menstrual flow begins, the activities of all the organs are augmented. Nervous and vascular tension is increased; the heart's action is increased in strength and rate, and a general vascular turgescence is manifested in all the blood-vessels. The liver is doubtless at this time also hyperemic. As the flow approaches, however, these activities begin to abate, and so continue until near the close of the flow when the minimum is reached. As the amount of blood lost per twenty-four hours averages only from 25 c.c. to 50 c.c., the mere oozing of blood at the menstrual epoch *per se* can have little or no effect upon the blood pressure for the loss is probably compensated for as rapidly as the blood is lost.

The uterine blood-vessels have no direct connection with the portal system, therefore a sudden stoppage of the flow from the uterus could not affect the liver by any damming-up process.

As to hemorrhoidal bleeding, while there is a direct communication between the hemorrhoidal veins and the liver, the first effect produced upon the liver by hemorrhoidal bleeding would be that of anemia, and a sudden checking of the hemorrhage could scarcely do more than set about the normal conditions. In this connection, it will be remembered that hemorrhoids are often the products of portal engorgements, in which instance the liver may be hyperemic during and after the hemorrhage, and a wrong impression may be obtained upon examination after the hemorrhage is checked. The overloaded portal system invites sluggish absorption, the capillaries of the intestines become congested and a general catarrh of the mucous membrane results.

Stagnation of blood in the smaller vessels encourages thrombosis and as a result of infected emboli, suppurative infarcts may occur in the spleen, bowel, stomach or gall-bladder. In the early stages of hyperemia the liver is uniformly enlarged. As the process advances the liver cells atrophy, leucocytes infiltrate the lobule, and foci of fatty degeneration and pigmentation is the ultimate result. The marbled appearance at this stage, has given it the name of "nutmeg liver."

Fatty infiltration and fatty degeneration afford an interesting study for both the pathologist and clinician. It must be remembered that a certain amount of fat is normally found in the liver cells, it being formed from the stored carbohydrates probably by a fat enzyme in the liver, which converts a portion of the glycogen directly into fats, and it is with some difficulty that we are able to distinguish fatty infiltration of morbid nature from that of the normal product.

Moreover, it is not always easy to differentiate fatty degeneration from fatty infiltration. As this, however, is a matter of technic, it will not be indulged in further at this time. Many drugs are known to be productive of fatty degeneration, viz., phosphorus, arsenic, mercury, camphor, chloroform, etc. Phosphorus poisoning, thanks for the stringent measures now enforced in the manufacture of lucifer matches is nowadays rarely a cause. Fatty infiltration is often found in those who gormandize in food and drink and lead sedentary lives. Overfed infants, especially if carbohydrates form the bulk of the diet, are liable to fatty liver. In such cases there is undercombustion of fats and carbohydrates, taken as food.

When large quantities of alcohol are imbibed, the oxygen is used in burning up the excess, and fatty infiltration may result. In this connection it must be remembered that the liver is a fat conservator. The organ, however, has not acquired due credit for this function. Indeed, it has been spoken of as rather a paradoxical fact, that fatty infiltration and degeneration are frequently found in the cachexias, such as tuberculosis, chronic suppurative bone disease, cancer, etc. Much of the fatty infiltration found in these affections, in my opinion, may be a normal conservative process, the fat being merely held in reserve as a final source of energy, and is given up to the system as necessity demands.

So long, however, as the genesis of fat itself, both from a physiological and pathological standpoint remains undetermined, these problems must remain *sub judice*.

Cirrhosis of the Liver.—While many factors seem to be responsible for cirrhosis none will produce the changes met with except they be long continued. Alcohol, for instance, may be taken in large quantities for a considerable period of time, without any apparent harmful effect upon the liver tissues. It is only when it is long continued that pathological changes are manifested.

Changes in all probability do occur, but they are recovered from, and the precicatricial stage averted. Recent investigations have proved that the liver tissue possesses a remarkable capacity for regeneration.

There is reason for the belief that all liver cirrhosis is the result either directly or indirectly of infection. Especially is this true of the biliary or obstructive type. That alcohol and other intoxicants act in a manner to lower the cell resistance cannot be successfully denied, but if it were the specific cause of liver cirrhosis, we would at all times expect to find the disease present in chronic alcoholics, which is by no means borne out. It is well known that the normal liver harbors bacteria, and the avenues by which infection may reach the liver are so many that we may expect to find either bacteria or their toxins quite constantly present in the organ in health and in disease. It is not essential, however, that the propagation of bacteria takes place within the liver, for this process may occur in other organs of the body, but their toxins nevertheless readily reach the circulation and thus are transported to the liver, and in their effort to eliminate or render them harmless the liver cells finally fall martyrs to the system, in whose interest they have been struggling.

Fibrous and connective tissue fills in the gap caused by the broken down cell, and cirrhosis is the result.

In biliary or obstructive cirrhosis the parenchyma of the gland is destroyed as a result of the closure of the excretory canal. Such conditions may follow congenital absence or malformation of the hepatic duct, in which case the toxins are retained in the liver.

Other cases are doubtless due to direct infection and may take place very early in childhood or infancy. According to Lovett Morse (*Medical Record*, September 20, 1902), all forms of cirrhosis met with in the adult also occur in childhood. There are also forms peculiar to childhood. The disease is not common but occurs oftener than is generally supposed. The ordinary forms usually occur between the ages of nine and twelve years. All the etiological factors of adult cirrhosis play a part in the causation of the disease in childhood. Congenital syphilis plays a frequent rôle.

Alcohol is undoubtedly responsible for a large number of cases of childhood cirrhosis. Unsuspecting and ignorant parents who permit their children daily to indulge in the family wine cup, have no realization of the true dangers lying in wait.

That abnormal fermentation in the bowels is responsible for a large percentage of cirrhosis in children as well as in adults there is little doubt. The fact that cirrhosis of the liver has been found in several children of one family would lead to the conclusion that the cause may sometimes lie beyond the natal state. Toxic matter circulating in the blood of the mother undoubtedly may affect the fetus in utero, leading ultimately to liver infection.

But little light has been shed upon the true nature of the pigmentary cirrhoses. Owing to their being so often met with in diabetes, some investigators have sought to establish a connection between them. For a long time the glycogenic function of the liver, as defined by Claude Bernard, remained unquestioned in its entirety. Reasons, however, are now apparent, which demand a slight modification of this theory. This hypothesis assumes that glycogen is stored up in the liver and is given up to the system after being converted into a monosaccharid, whence it was originally obtained. The effect of these transpositions being to maintain a definite percentage of sugar in the blood, any excess of the normal proportion of dextrose circulating in the blood, according to this hypothesis, stimulates the liver cells to convert and store the carbohydrates as glycogen in the liver, and on the other hand, a diminished percentage creates tissue hunger, and causes the insoluble disaccharid to be transformed into the soluble, and in this wise nourishes the system with a definite proportion of carbohydrates.

That these processes actually take place is believed to be true, but it has been further shown that glycogen may be obtained from other sources, and that at least a part of the molecule is converted into fats. This brings us to the part which the liver may play in diabetic affections. Any distubance of the glycogenic function of the liver will permit an excess of dextrose to circulate in the blood. The kidney tolerates only the normal percentage of sugar in the circulation, and when any excess is reached, it is promptly excreted in the urine. Pavey believes that glycogen is converted into proteid, and that the nitrogenous part of the proteid molecule acts as a carrier for it.

He contends that one of the chief functions of glycogen is that of a proteid sparer, and that as a result of this office of the liver cells passing into abeyance, diabetes ensues.

This furnishes a satisfactory explanation of the persistence of sugar in the urine in diabetes, after cutting off all carbohydrates diet. If the proteid molecule is, as some physiological chemists assume it to be, a union of a carbohydrate with a nitrogenous rest, we can readily see how the vitiated metabolism of the liver cell may, by a simple reverse process, set free dextrose from the circulating proteid.

THE BEST METHOD OF DEALING WITH THE STUMP IN APPENDICECTOMY.

BY HOWARD LILIENTHAL, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO MOUNT SINAI HOSPITAL, NEW YORK.

The simplest way, which has proven efficient, must be conceded to be the best. Yet on theoretical grounds many surgeons have found fault with this simple method and have advised the employment of numerous other forms of technic, all of them more or less complicated, several of them

very wasteful of time and some of them distinct sources of additional danger to the patient.

While it is not my intention here to go into the criticism of the other methods, I desire to answer at least two of the objections which have been urged against the ligation and cauterization of the stump.

It has been stated, evidently on theory and not from clinical observation, that when the appendix is ligated mucous surfaces are brought in contact and that inasmuch as mucous membranes will not adhere to each other, the stump thus formed is insecure. Now, as a matter of fact, when a tight ligature is placed around the root of the appendix the mucous lining is crushed and destroyed at the point of constriction. For all practical purposes we may consider that the mucous membrane is cut by the ligature which is held in place by the tough submucous fibrous tissue and the peritoneum. I have shown this to be the fact by observations on vermiform appendices examined immediately after their removal, an additional ligature having been applied before the ablation for the purpose of this study and I have also examined several appendices sectioned longitudinally after hardening them in alcohol. The recent specimens demonstrated clearly not only that the ligature was absolutely secure but that the mucosa had been cleanly cut, although theoretically it had been pulpified by the constricting ligature. In each case the submucous fibrous coat and the peritoneum were uncut and held firmly. The hardened sections confirmed these observations.

In cases in which there is great infiltration of the walls of the appendix with friability it is best to crush bluntly the rigid root of the organ with a clamp or forceps and then apply the ligature to the crushed tissues. If there is complete gangrene at the base of the appendix, this technic, of course, cannot be employed.

Now, as to the second criticism: Certain writers have maintained that adhesions are apt to form with a stump of the kind I have described. This assertion I feel convinced has also been made on insufficient evidence. It has been my fortune to have the opportunity of examining into the postoperative conditions in a number of cases treated by ligation and cauterization. Three cases of fatal peritonitis examined from three to six days after the operation showed adhesions almost everywhere else but *not* at the stump, which could not be found at all. It had been cast off with its ligature and only a smooth cicatrix on the surface of the cecum remained. In a number of other patients upon whom operations for other conditions were undertaken, months or years after the removal of the appendix, most of them for adhesions when peritonitis had existed at the time of the primary operation, the former site of the appendix was marked by a minute smooth white cicatrix. No adhesion was ever found in this location, no matter how numerous they were in other parts of the abdomen. The stump, formed as herein described, is cast off in from three to six days and with it any temporary adhesion which may have formed disappears. It is therefore my belief that the formation of the stump by the method of ligation is the only way in which adhesions at this point may with certainty be avoided.

The cauterization which for many years I have preferred is that by strong carbolic acid. A minute drop of the 95-per-cent. solution is taken up with a closed artery clamp as ink is taken up with a pen and after protecting the surrounding tissues with gauze the acid is thoroughly applied two or three times to the mucous lining of the stump until the little funnel is completely whitened. In from fifteen to thirty seconds the stump may be dropped back into the abdominal cavity with no danger to other structures which may come in contact with it.

This rapid, simple, safe and thoroughly surgical method is warmly recommended to the profession after the satisfactory test of ten years, in many hundred cases.

766 Madison Avenue.

CHRONIC VILLOUS ARTHRITIS, WITH SPECIAL REFERENCE TO ITS ETIOLOGY AND PATHOLOGY.

BY CHARLES F. PAINTER, M.D.,
AND
WILLIAM G. ERVING, M.D.,
OF BOSTON.

(Continued from Page 980.)

Postoperative Treatment.—The postoperative treatment is fully as important as any which has preceded it. Unless there are indications to the contrary, dressings are not disturbed for one week, when the stitches are removed, and passive manipulation is begun at once.

The cases vary considerably with respect to early restriction of motion, and they seem to vary directly in proportion to the size of the bases of the pedicles from which the fringes depend. In other words, the more vascular the pedicle which connects the villus with the general synovial membrane, the more extensive is the denuded surface after the fringe has been excised, and, where there are a number of these broad denuded areas, adhesion seems to be more likely to occur. These adhesions, however, are very slight, and are readily overcome in most patients without an anesthetic, and, when this is necessary, but one, or at most two, manipulations under gas are required.

Passive manipulation by the patient and active manipulation by the physician should be practised daily during the second week. At the end of this time motion is usually restored to ninety or more degrees. It is then safe to allow the patient to begin to bear weight on the leg, and to encourage him to walk, supported somewhat by a crutch or cane and wearing a compression bandage, such as is made from Shaker's flannel. Daily hot and cold douching stimulates the joint, and facilitates its restoration to normal functional activity.

Some soreness and stiffness persists often for

a longer period than this, but, ordinarily, at the end of the second or third week the active treatment of the joint should be practically completed. Subsequent visits are usually unnecessary.

Pathology.—The appearance of these hypertrophied joint fringes ranges within wide limits. The smaller are of a reddish-gray to purplish color, of delicate dendritic appearance, attached to the synovial lining of the joint by an extremely slender and delicate pedicle. They are present in great numbers, presenting a fungus-like appearance over the entire membrane. Their consistency is very soft and yielding, and their vascularity is especially marked.

At the other extreme are the large, irregular, coarsely lobulated, yellowish fatty masses of 4 to 5 cm. in diameter, often glued by constant inflammation to the synovial lining over a wide area, though the original pedicle is generally to be distinguished. These are usually but one or two in number, and occupy the greater part of the joint cavity. More rare are the fatty masses without any trace on inspection or palpation of fibrous tissue, and the masses of hyaline necrotic tissue or of connective tissue infiltrated with bone or cartilage cells. Between these limits are all shapes and sizes, the pedunculated appearance and rich supply of vessels being the most common characteristics.

On section the tissue even in the larger growths is very rarely of a true fatty consistency. There is always a resistance characteristic of the presence of fibrous tissue in some amount, which in a few instances passes into the gritty solid resistance of bone and cartilage.

A microscopic examination of the smaller growths shows the pedicle to be composed of numerous parallel blood vessels imbedded in a mass of small round-celled tissue, with a thin endothelial lining. Following this to the enlarged bulbous end, the periphery of the growth is found to have the same nature. The cortical portion is composed of an endothelial lining, consisting of a single layer of cells, and a connective tissue groundwork infiltrated with the small round cells characteristic of a chronic inflammatory process, often arranged in definite whorls, somewhat resembling a tubercle. But these whorls never contain the characteristic round epithelioid cells, the giant cells, or the necrotic areas, characteristic of tuberculosis. Minute blood-vessels are very numerous. A short distance from the outer border of the fringe, fibrous tissue begins to predominate over the small round cells, and this shortly gives way to adipose tissue of normal appearance, which constitutes the remainder of the growth. This is not pure adipose tissue, however, for at intervals appear striæ and irregular collections of more or less normal connective tissue, associated with blood-vessels. Although usually these bands are definite and stain deeply, yet often they stain but feebly, and show evidence of granular necrosis. The vessels, very numerous throughout, show, especially in the central portions, marked endarteritic changes, and, where the adipose tissue is most abundant, the vessels are very small, and their lumina are very frequently obliterated.

These same appearances hold true even in the largest fatty growths, save that in these cases the peripheral layer of small round cells is much thinner and at times almost entirely absent, while the areas of unbroken fatty tissue tend to increase in extent. Occasionally, and in apparently very chronic cases, the specimen shows a mass of unbroken fatty cells, with no patent blood-vessels, though occasionally traces of their walls which have undergone hyaline necrosis are to be distinguished. Here, too, are found irregular patches of former fibrous tissue which have become hyaline,—a condition which is universal throughout the fringe in rare cases of many years' standing.

Bone and cartilage cells were found in but one case, but here they formed definite areas of large size. In no case were any signs of tuberculosis apparent, nor is there any tendency to the formation of malignant new growths, though instances of the former are plentiful and of the latter not unknown in the literature.

Prognosis.—The question of the prognosis in these cases cannot, we think, be definitely spoken of as yet because of insufficient data on the subject. It must be borne in mind also that, in giving a prognosis, account must be taken of the cause of the villous hypertrophy. The operation cannot be justly condemned as a surgical procedure because a latent general disease has been overlooked by the operator. In the traumatic cases, and those due to faulty weight-bearing, there is every reason to look for a good result, provided, of course, that in the latter case the defective mechanics are corrected. Neither is it fair to expect or to lead the patient to expect a cure of rheumatoid arthritis to follow the simple removal of large masses of fringes from the knee-joints. In this and allied diseases causing villous arthritis the most that can be held out by way of encouragement to the patient is the hope that, by improving the function of a large joint whose integrity is vitally concerned in promoting the individual's general welfare, the individual may put himself in a position the better to overcome the diathesis. In many cases this can be accomplished, in others it cannot. So far as the cases here reported can afford any basis for a prognosis, bearing the before-mentioned circumstances in mind, and remembering the comparatively short time which has elapsed since the date of operation on the first of the series, it seems fair to claim that in the traumatic cases the prognosis is very good, whereas in the diathetic cases it is impossible to obtain very brilliant results. The long standing cases are apt to suffer from a condition of marked joint relaxation, which requires some after treatment tending to the strengthening of the muscles and shrinking up of the capsule; and this takes time. In one of our cases, where the fringes had developed directly beneath the patellar tendon, they had attained such size as to crowd the tendon forward and pre-

vent its coming perfectly straight in extension of the leg. This patient has had some difficulty in recovering complete voluntary extension, apparently because of this elongation of the patellar tendon. Abbott, in a recent article, speaks of a paralysis of the quadriceps extensor which has not been observed in our cases.

REVIEW OF LITERATURE.

The following represents the reports of cases reported by various authors.

Pathological text-books deal very lightly with the subject.

Ziegler presents an illustration of the museum specimen of lipoma arborescens described by Stieda.

Billroth mentions the fatty development in synovial fringes of joints, the so-called lipoma arborescens, as being a very rare condition.

Coplin believes the condition to be a step farther than cloudy swelling in the process of fatty degeneration. He considers it as developing in subserous or subsynovial tissue and pushing its way into neighboring cavities.

Delafield and Prudden refer to lipoma arborescens as a tuft of synovial membrane pushing into the joint, while by Hektoen-Riesmann the old theory is advanced that these growths are signs of some underlying cause, as tuberculosis, or osteo-arthritis.

Goetz, writing in 1798, was the first to describe the condition. He spoke of numerous thread-shaped and hydatidiform processes springing from the inner aspect of the synovial membrane of the knee-joint. They were rich in fat, suspended by slender threads, covered with a thin membrane. The larger ones had enlarged saccular ends filled with lymph. These fringes floated in the joint fluid suspended by their stalks.

Johann Müller, in 1838, first gave the name of lipoma arborescens to pendulous fatty processes hanging about the synovial fringes of chronically inflamed joints.

Solly, 1848, reported removal of several small bodies from elbow-joint of a man of fifty-nine years. First palpated nine months before, preceded and followed by distinct rheumatic attacks with inflammation and limitation of motion. On examination by Rainey these tabs were found to be enclosed in a membrane of fibrocellular tissue mixed with granular matter, while the central portion consisted of fibrocartilage and osseous tissue. They were attached to the synovia by pedicles and were very vascular, consisting of capillary sacculi and secondary sacculi without capillaries. He believed them to be products of disease of the synovial membrane, but of the exact nature of their formation he was in doubt.

Volkmann, in 1865, referring to lipoma arborescens, as being hypertrophied synovial fringes which had undergone fatty degeneration (sometimes cartilaginous), gave an illustration of the knee-joint specimen in the Anat. Museum of Halle, to which J. Müller first applied the term, and which was originally described by Goetz.

Simon, in 1865, reported a case of arthrotomy in an adult male for painful swelling and attacks of sharp pain on using knee. A large joint body could be palpated on inner aspect of joint. At operation this was found to be attached by a very vascular broad pedicle to the synovia of outer side of joint. The growth was removed and a normal functional knee was the result. The growth was 5 x 1.5 cm., smooth, bright red, and covered with prolongation of synovial epithelium, consisting of fibrous tissue with areas which had undergone fatty change, while the whole showed involvement by a sarcomatous process of the giant cell type. He considered it a hypertrophied synovial fringe which had become sarcomatous.

Volkmann, in 1873, reports the case of a sixty-three-year-old man with beginning arthritis deformans with symptoms of one and one-half years standing. Growth excised, found to be pedunculated, size of cherry, in outer side of joint, near upper part of patella. Growth fatty, perhaps developing from a fringe. General condition grew worse.

Boyer, in 1877, reported an autopsy in which there was considerable thickening of the synovial membrane of the right knee, its surface entirely covered by a large lipoma arborescens. In addition there were numerous pedunculated fringes, many of which contained cartilage and bone cells. A similar but less marked condition existed in the left knee. The joint surfaces of tibia and femur were eroded and osteophytes were present. In life knee had been stiff for some time.

Riedel, in 1878, reported two cases of solitary lipoma in knee-joint. Both occurred in young adult women, the first of nine months' duration following severe strain to knee, the second of thirteen weeks, no cause given. The results of excision were excellent. The specimen from the first knee consisted of a flat mass of fatty tissue lying lateral to the patellar tendon, attached to joint wall by stalk passing under and across front of joint. The second consisted of a walnut-sized body of firm consistency. The prolongation extended upward between fibers of the quadriceps. Both specimens consisted of pure fat tissue with a thick covering of cellular tissue.

Patterson, in 1879, reported a case of partial lameness and disability of eighteen months' duration following strain of knee in lifting. The body, which was palpable, was found at operation to be the size of a bean, lobulated and composed of cellular tissue, attached to the synovial membrane by a short pedicle, and associated with a small amount of synovial fluid. Healing uneventful; result not given.

Danzel, in 1879, reported a case of removal of a bean-sized hypertrophied fringe in the knee-joint of a healthy middle-aged woman. The symptoms were pain, locking, and weakness of joint. The body was palpable at intervals, was found at operation associated with clear, straw-colored fluid in joint and attached by a long pedicle to the synovial membrane, and was removed with an excellent functional result.

Godlee, in 1881, reported the case of a woman, with a swollen, painful, and tender knee, of eight years' duration, in which a large movable body was palpable. At operation this was found to be a pedunculated mass, 1¼ x ¾ of an inch in extent, attached to the synovial membrane. Microscopically it was fibrocellular in structure, appeared to be covered with smooth synovial membrane, and the opinion was "hazarded" that it was an inflammatory thickening of a normal synovial villus.

In 1882, in a discussion following a report by See of a case of chronic arthritis treated successfully by iodoform injections, Lannelongue contended that tuberculosis was not the cause of all cases of fungous arthritis, but that some were undoubtedly rheumatic in their origin, and that there were probably other clinical varieties.

Barwell, in his article on the joints in the Internat. Cycl. of Surgery, 1884, referring to movable joint bodies, mentions one group, taking its origin in the hypertrophied fringes of the synovia. These growths are dendritic in appearance, often containing cartilage cells, and nodular formations, and sometimes become loose bodies, due to the breaking of their slender stalks. In this group he includes lipoma aborescens and single and multiple lipomata of similar origin.

Lauenstein, 1884, reported two cases of solitary lipoma in the knee joint. The first in a girl of seventeen, the onset occurring three years after an operation on the lower end of femur. For a year the knee had been swollen, painful, locking at intervals, with marked disability resulting. A mass was palpable above and to the outside of the patella. This was found attached to the anterior aspect of end of femur, and was removed. It was a fatty mass, 3.5x2x1 cm. in dimensions. Recovery uneventful, with perfect function of knee in about a year.

The second was in the case of an adult operated on for uniting the fragments of a patella fractured a second time. The joint capsule was found torn and joint was opened. Sanguineous fluid escaped, and in lower portion of joint behind the patellar tendon was found a fatty mass connected with the lig. cruciata and the intercondylar fossa through a synovial tear. It was very vascular. It was removed and patella fragments united. A functional knee with flexion to a right angle resulted.

He believed that the condition results from the tearing of the synovia by strain or blow and the entry of subserous fat into the joint.

Weir, in 1886, reported three cases of hypertrophied synovial fringes removed from knee-joints. All were without known cause in healthy young to middle-aged adults, and had persisted from one to three years. All were associated with swelling, tenderness, weakness, pain, or locking of joint. On removal they were found to be fatty, yellow-pink, irregular masses, very vascular, and from 1 to 3 cm. in diameter, attached to the synovial membrane by pedicles. Histologically the first showed chronic inflammatory condition with fatty and fibrous changes, while the other two had undergone sarcomatous transformation. In the first case sepsis intervened and amputation was resorted to with success, in the other two good functional result and absence of symptoms were obtained, without recurrence in the second case for at least two years.

König, writing in 1886, expressed the belief that lipoma arborescens was the result of a chronic inflammatory condition of which tuberculosis was the primary cause. This he did not consider a true lipoma, but he considered that a true papillary lipoma of the joint did exist which he saw in old cases of arthritis deformans.

Schmolck, in 1886, reported two cases of twelve and fifteen years' standing, with swelling and pain. On opening the first, numbers of dark to yellowish-red fringe-like bodies were exposed, of varying shapes and sizes, one large bundle being attached to the synovia by a broad base some 5 cm. in diameter. The second at operation showed the synovia thrown into deep dark red folds and covered with hundreds of hypertrophied fringes. Microscopic examination showed fresh miliary tuberculous process in both, evidently superimposed on the chronic condition. Schmolck contrasted these with several previously reported cases of isolated liponata of joints, but was not positive as to the truth of the theory advanced by König and Riedel, that these solitary forms were subserous in origin, as contrasted with the lipoma arborescens of Müller, which was simply a condition of hypertrophied fringes.

Haumann, in 1887, reported a case in a man with a rheumatoid history of eighteen years' duration. On opening the joint large outgrowths, resembling bunches of grapes, were found attached to the synovia and composed of ordinary fatty tissue, which he considered to be hypertrophied joint fringes. No tuberculosis present. He believed the condition to be the result of a chronic inflammatory condition, as arthritis deformans, or joint syphilis. He considered that the condition favored the invasion of tuberculosis.

Sutton, in 1888, reported on two dissection specimens of joints, the first of a shoulder-joint in a case of chronic osteo-arthritis, which showed attached to the margins of the glenoid fossa numerous pedunculated processes, varying from simple villous fringes to pedunculated masses of fat. The second was from a femoral condyle of a specimen in the Royal College of Surgeons Museum, showing a similar condition. He believed the condition to be simply a fatty degeneration of the villous fringes so frequently seen in osteo-arthritis (rheumatoid arthritis).

Shattock, 1888, reported a case of pedunculated body removed from knee-joint. It was attached to synovial membrane, was white, blotched with red, 3.2 x 7 cm., in a thin connective tissue capsule. Histologically it consisted of a faintly staining meshwork of nebulous granular substance with patches of pigment, simulating true fibrous tissue. He considered it the product of an old hemorrhage into the alar ligament.

Bazy, in 1890, reported the case of an adult male with an enormously swollen knee, the arc of motion much restricted. At operation numerous fatty polypoid growths, purple to yellowish in color, associated with a few osteophytes on the femoral condyles, and considerable clear fluid and fibrin flakes. Healing uneventful and result not given. The specimen was a typical lipoma arborescens, the periphery composed of small round cells interspersed with many vessels, the central portion cellular adipose tissue with large vacuoles, and islands of granular material. No evidence of tuberculosis. He believed the condition to be of a chronic inflammatory nature.

Patterson, in 1890, referred to lipomata arborescentia of joints as the hyperplastic increase and subsequent fatty degeneration of normal villi of the synovial membrane, as distinguished from the pure lipomatous bodies in the joint which originate from the subsynovial fatty tissues. He considered that the loose fibrous bodies found in joints were originally hypertrophied villi which had become detached.

Israel, as quoted by Stieda, reported a case of swelling and pain in knee dating from a trauma six months previous. At operation he found the richly-vascular, fat-infiltrated, hypertrophied synovial fringes, the type of lipoma aborescens. No sign of tuberculosis. Excellent functional result.

Robson, in 1891, reported case of a sailor who had an intermittently painful knee, much swollen, following a trauma two years previously. No foreign body was palpable. Associated with much straw-colored fluid he found three pedunculated masses, the largest the size of a hen's egg, irregular, lobulated, fibrous in character, with a covering of synovial membrane. These were removed and a perfectly functioning painless knee resulted. He considered it a genuine fibrous polyp, originating in deeper synovial layers, and not an hypertrophied synovial fringe, which, though occasionally pedunculated, would seldom attain such a size.

Modunski, in 1891, reported a case of a tuberculous patient with swelling of knees of ten years' standing. In both knees were found typical lipomata arborescentia, infiltrated with caseous tubercles, while in one knee there was erosion of the cartilage. No microscopical examination.

Blachian, in 1893, reported a case of painful swelling of left knee, with limitation of motion, these attacks occurring at definite intervals of a few days with almost complete disappearance of symptoms between attacks. The condition was without known cause, but occurred five years previously in connection with an acute arthritic attack in shoulder, which disappeared under salicylates. It had become so severe as to seriously incapacitate patient. On opening the knee a small amount of clear fluid escaped, and a large number of fringes appeared, which took their origin from the synovial membrane. These were removed and a perfectly functioning painless knee resulted.

The outgrowths were typical synovial fringes, lymphoid and fibrous tissue predominating in the smaller, while the larger ones, consisting of fat cells, in a meshwork of fibrous tissue. They were all very vascular, and enclosed in an endothelial covering. He considered them typical examples of lipoma arborescens, taking their origin in the synovial membrane, not from deep tissue driven into joint; that in some cases tuberculosis might complicate the process without being its cause, and that the condition could result from trauma only if hemorrhage into joint occurred at the time. In this connection he cited a case reported by Brockelmann, in which a boy with a hemophilic tendency was operated on for acute hemarthrosis and died shortly after. At autopsy the synovial tabs of both knees showed marked hyperplasia, with brown patches of pigment, the starting point of a future chronic villous hypertrophy.

Dor, in 1893, cited a case of lipoma arborescens in the shoulder-joint of a man of forty-one years, suffering from arthritis deformans. From this he cultivated *Staphylococcus pyogenes albus* and a gelatine liquefying organism. From this he concludes that certain forms of arthritis deformans are of infectious origin, and that these organisms are the cause of the accompanying villous hypertrophy.

Le Bec, in 1893, reported a case in the knee of a girl of thirteen, following a fall with ensuing synovitis four years previously. Pain and swelling resisted conservative treatment, a palpable mass persisting. At operation he removed a mass of brown-red fringes two to six cm. in length, attached by pedicles to the synovial membrane, which were demonstrated microscopically to be of a purely fatty nature.

Schüller, writing in 1893, states that he found synovial fringes of varying size in normal joints, never, however, developed to such a degree as to be palpable externally, and not in great numbers. He carefully described the anatomy and histology of the enlarged fringes of chronic rheumatoid arthritis and believed that the term lipoma arborescens as applied to these cases should be abandoned as a misnomer, the condition being one of chronic inflammatory hypertrophy and not a new growth.

Riedel, in 1893, examining the knee of a patient in whom a healed periarticular tuberculous process was demonstrated microscopically, found great numbers of hypertrophied synovial fringes of the type of lipoma arborescens without trace of tuberculosis. He believed that there was originally a circumscribed intra-articular tuberculous process which first caused the fringe hypertrophy. He cited a case of removal of fringes from an otherwise normal shoulder-joint, where there was a tuberculous focus in the humeral head. One year later tuberculosis developed in the joint. These cases were first reported in 1891, together with a note on a third case, in which at operation a "fibroma arborescens" of the elbow-joint was found. No trace of tuberculosis was found in this case on microscopical examination. The patient was a girl of seventeen with marked tuber-

culous glands of the neck. He noted that the condition may develop in the wake of a tuberculosis, arthritis deformans, simple serous arthritis, or any chronic inflammatory condition of a joint.

Sokoloff, in 1893, reported two cases of chronic swollen painful joints in adults, the first of two and one-half years duration in the knee, the second of recent date in the elbow. In the first arthrectomy done with good results, in the second erosion with death from sepsis. In both were found typical hypertrophied fringes of small size in great numbers, with tuberculous infiltration of the tissue in the first. Sokoloff was of the opinion that tuberculosis was responsible for the condition in both cases, though found only in one. In a second article, published in 1893, he offered another etiological factor in fringe hypertrophy. He referred to the recent work of O. Hagenhorn and Schüller, who showed the presence of synovial fringes of small size in certain portions of all normal joints, and the developmental atrophy of these fringes in parts of the joints subject to pressure from the articular bony surfaces. Thus, when the intra-articular pressure was least, the fringe development was greatest. In this connection he reported two cases, one operative and one anatomical, of old non-reduced dislocations of femoral head. In both cases there was marked hypertrophic condition of the synovial fringes in the upper outer portion of the joint capsule, which was much dilated, and which was without function. These fringes were most abundant and had undergone extensive fatty degeneration.

Sokoloff believed that any pathological diminution of the normal pressure conditions was sufficient to cause this hypertrophy of normal elements, without any additional inflammatory process.

Vibrac and Faquet, in 1894, reported a case in which arthrotomy of knee was performed for relief of symptoms of foreign body in joint, following trauma two years previous. A typical lipoma arborescens and some free osteophytes were found, the former believed to be the result of the irritation of these foreign bodies. In the discussion M. Anchi referred to a case of coxafemoral arthropathy with numerous fatty synovial fringes. Some were terminated by fibrous nodosities, which were hard and infiltrated with cartilage cells, while others had become detached.

Stieda, in 1896, reported two cases, the first an operative case which dated from an injury to the knee several years previous. Resection of the joint was done with good results. The second was a museum specimen, a hip involved by arthritis deformans, which showed a marked lipoma arborescens. Microscopically, the periphery of the growths was composed of small round cells, and the central portion of adipose tissue interspersed with fibrous bands. Throughout were very numerous vessels, with thickened walls. He distinguished this condition from that of single or isolated lipomata of joints. These latter he stated to be composed of pure lipomatous tissue, presumably originating in the subsynovial tissue, which entered the joint cavity only through a laceration of the capsule. He believed the lipoma arborescens to be a hypertrophy with fatty degeneration of normal pre-existing tissue, caused by chronic inflammatory condition of whatever etiology, and not peculiar to any one disease. He considered operation, often of a radical nature, the only satisfactory treatment.

Halstead, in 1896, writing on floating bodies in the joints, referred to the pathological metamorphosis of normal joint villi and their subsequent detachment from the synovial membranes occurring in arthritis deformans and other forms of joint disease. This condition he distinguished from loose cartilage and true foreign bodies in the joint which have brought about a pathological condition in a previously normal joint. He gave as a clinical picture of these conditions sudden locking of joints, usually in extension, a recurring synovitis, at irregular intervals following an acute attack, and crepitation in joint.

Bolton, in 1896, on reviewing the literature, found 720 cases of arthrotomy for foreign body in the joint, and referred to the treatment of cases of the type of lipoma arborescens and hypertrophied fringes. Although he found unsatisfactory results in a large per cent. of these ceses, he nevertheless advised removal, tying of stumps if necessary, drainage only in extensive synovitis, or in severe hemorrhage from manipulation, and postoperative immobilization by splint or plaster.

Schüller, writing in 1900, in elaboration of his article in 1893, advanced the claim of a bacterial etiology of chronic villous arthritis, which he classified as a distinct disease. He took this stand from his observation that a chronic villous arthritis occurred often in the absence of any general disease, such as arthritis deformans. The condition he characterized as an hypertrophy of the fibrous and fatty elements of normal synovial villi, and their subsequent fatty degeneration following a chronic inflammation of the synovia. This inflammation he concluded to be caused by a certain bacillus, which, sometimes associated with a coccus, he found in villi thus affected. This he was able to grow in pure culture, and inoculate into the joints of animals with the subsequent appearance of similar synovial changes, associated with the presence of similar bacilli in the inflamed villi. The coccus he considered unimportant. No further work has been done to substantiate his claim, which appears scarcely conclusive in itself.

Goldthwait, in 1900, drawing conclusions from 38 arthrotomies of the knee-joint, mentioned the fact that in nineteen cases coagula or hypertrophied fringes or folds of synovia were found in the joint. He believed these fringes to be due to a chronic inflammatory condition of the synovia, with increase of blood supply and resultant hypertrophy of the membrane, which was able to expand in one direction only, due to the unyielding nature of the capsule, with the resulting formation of vertical folds. These folds slipped over each other, causing cracking and snapping,

or caught between the articulating bony surfaces, particularly below the patella, with locking of the joint. Trauma of this nature, frequently repeated, tended to perpetuate and increase this inflammatory condition. With prolonged irritation degenerative changes occurred, the fibrous tissue normally found giving way to bone and cartilage or to fatty tissue, especially the latter. Coagula, so frequently found in connection with this condition in the joint, he considered an end result of a former effusion, and believed that acting as a foreign body in the joint it was often the cause of the chronic inflammation. In cases where the condition was due to relaxed joint ligaments, he believed that strapping with resulting prevention of the intermittent trauma often caused the condition to disappear, but in most cases he recommended incision of the joint, excision of the fringes, irrigation with hot water, tight closure and immobilization. Immediately after removal of stitches, bathing, passive motion, and manipulation were to be practised. The prognosis was good in cases where the condition was due to local causes, but where due to an underlying general disease, it varied directly with that of the disease itself.

Abbot, in 1903, reporting 12 cases of hypertrophied fringes, 8 treated by operative measures, considered trauma to be but an occasional cause. He believed it to be the result of some fault in weight-bearing structures of lower extremity, especially a flattened arch, which he had found in all his cases. This led to straining of ligaments of joint, the meeting of articulating surfaces in abnormal positions, and the consequent pinching of normal synovial tabs, with a resulting chronic hypertrophic inflammatory condition. He found very vascular, dendritic, fibrous fringes, rich in cells, and associated with a varying amount of fluid, usually very slight. No micro-organisms, but a simple inflammatory condition. He noted the swelling, locking and pain in joint with frequent loss of function. On examination, no redness or heat. Swelling usually most marked on inside of joint. Movement possible beyond normal limits, lax ligaments, some lateral motion. For conservative treatment he advised hot air, strapping, correction of pronated feet, a brace to limit lateral motion. Immobilization of joint was condemned. The operative treatment consisted in excision of fringes, immobilization in plaster for two weeks, followed by manipulation. The after results are excellent. He found no foreign bodies or torn cartilages in any of his cases.

Conclusions.—1. Chronic villous arthritis is not a disease of itself, as has been claimed by some authors. It occurs associated with chronic diathetic disease which involves other tissues than the synovial membrane of the joints affected, but it is representative in such cases of the same pathological changes which subsequently obtain in the other structures of the joint. The two principal diatheses which cause this are rheumatoid arthritis and osteo-arthritis. The villous changes in these two chronic conditions are to be regarded as symptoms of a general condition, and not as an entity in themselves.

2. Traumatism, entirely apart from any diathesis, is capable of giving rise to an hypertrophy of villi, and this hypertrophy is usually a local one in the part of the membrane directly or indirectly injured. The type commonly goes on to a dense fibrous growth, which keeps the joint in a constant state of injury through its traumatic effects.

Traumatism, associated with an osteo-arthritic diathesis, is frequently the excitant of local synovial hypertrophy; but the synovial changes are apparently more the result of the trauma than of the stirring up of the diathesis.

3. Stout, flabby adults, with pronated or flat feet, are more liable to the type of fringe which undergoes fatty degeneration with a minimum amount of fibrous change. This condition is sometimes associated with pregnancy, the tissue relaxations of nervous prostration, and the "soft" condition of so many rapidly growing and sickly children at the period of puberty.

4. Alteration in the mechanics of weight-bearing is not, as has been recently stated, the prime cause of this condition in many of the knee cases. It is very frequently a contributing factor, and as such should be given its full weight when questions of treatment arise; but it is extremely doubtful if simple flat foot or pronated foot without some more fundamental tissue change can account for this condition.

5. The operative treatment in the properly selected cases gives eminently satisfactory results when undertaken with an understanding as to what the procedure contemplates. Conservative treatment, when carried out properly in suitable cases, which comprise, however, only a small class, gives equally good results. The main thing is to be able to discriminate between the classes.

6. Judging from the pathological findings, the condition is the result of a chronic inflammatory process of whatever cause, which, by acting upon the normal villi of the synovial membrane, causes their hypertrophy, together with a consequent great increase in the number of their blood-vessels. This condition becoming chronic, due to the continuance of the toxic cause or to intermittent and slight trauma, the vessels are unable to supply the needs of the new tissue, affected as they are themselves by the inflammatory process.

The result is their gradual endarteritic obliteration with the almost complete loss of blood supply and the disappearance of the normal fibrous tissue, which either undergoes necrosis and hyaline degeneration, or disappears, leaving in its place tissues which can be nourished by a very limited supply of blood, the adipose being the most common form. In this necrotic condition separation of the pedicle and the formation of a loose joint body can easily occur.

PRIMARY OSTEOPLASTY IN OPEN FRACTURES OR FRACTURE DISLOCATIONS.

BY THOMAS H. MANLEY, M.D., PH.D.,
OF NEW YORK.

A WIDE field for osteoplastic procedure is offered in various types of open fractures. To this species of salutary, conservative surgery, we must turn now, as a substitute for primary amputation in a large number of severe traumatisms of the limbs or their appendages.

With the utilization of anesthesia, we may now proceed with deliberation and thoroughness in our examination. With effective hemostasis and surgical cleanliness we may take chances in saving a shattered limb without any disadvantage to our patient; but, moreover, we can preserve and restore many an appendage or limb which before the Lister period had to be sacrificed or retained in a distorted, useless shape.

Immediate Osteoplasty After an Open Fracture.—There are comparatively few extensive mutilations of osseous parts which permit of extensive or precise manipulation of them immediately after injury.

The patient is usually in shock, has lost freely of blood and is in a bad way to endure any tedious procedure under an anesthetic. Moreover, we are not always able at this stage to determine the degree of vitality in the parts mutilated.

There is a small number, nevertheless, which is in such a physical state as to warrant precise treatment at first examination.

After effective hemostasis and cleansing we may quite painlessly effect replacement of the fragments, and so close in the muscular or fibrous structures about them as to aid in their retention. We may remove detached fragments driven into the soft parts or forcibly pressing on the nerve or blood-trunks. If necessary, we may also drill the fragments, rivet or wire or peg them.

Fragments retaining periosteal, muscular or connective-tissue attachments, should be carefully replaced; the torn muscle, tendon or ligament may be sutured with fine gut. An effort should always be made to secure a *dry* and clean wound.

Drainage, by the use of sterile gauze-wick, may be employed when the wound is deep, and there has been extensive laceration; though in some it will be quite enough to leave the integuments freely open, or close them in by a few sutures only, in order to permit of a free escape of the secretions. The limb should then be embalmed in antiseptic dressings, placed in a flexed position and be comfortably supported.

When these cases escape infection, and there is no suppuration, in a sound subject, the primary dressing should not be disturbed for a week or ten days. In vigorous subjects, we may often look for surprising results.

Consecutive Osteoplasty After Open or Complicated Fracture.—The aim and purpose of consecutive osteoplasty are to overcome deformity and restore function. Immediately after many serious fractures, we are unable to estimate what the degree of resulting defect in outline or action of the limb will be.

There has been more or less local devitalization of the parts, hard and soft, and though widespread infection is under control, the dead tissues must be thrown off by sloughing or mortification.

In many open fractures time alone will determine how extensive the loss of tissue will be. Again, the limb may have been so badly crushed, that our energies must be concentrated on an attempt to save the limb in *any form*, the matter of shaping it, being an affair for further consideration.

We have another class of fractures in which consecutive surgery is capable of sometimes effecting superb results. These are cases of closed so-called "simple" fracture, followed by hyperostosis or deflexion of the fragments, with resulting damaging pressure on the nerve trunks, neuralgia, paralysis or hyperesthesia of the limb.

Several illustrative cases of this class have come under my notice; one a fracture of the clavicle with downward pressure of the callus on the brachial plexus; one of callus inclusion of the muscular spiral nerve in humeral fracture; one case of complicated fracture of the elbow and forearm with fusion of both shafts and a dislocated head of the radius; several in fractures of the leg and thigh.

Osteoplasty in Fractures of the Extremities in Close Proximity, or Involving the Articulations.—Osteoplastic resources are frequently useful in

effecting reposition, correcting deformities, relieving nerve pressure or overcoming deformity in various closed fractures, or in dealing with cranial or clavicular fracture, but their great forte is with the open or complicated, of the levers of the extremities.

We should invite no fresh complications by division of the tissues, unless they are already open, as it is with these latter, as a rule, there is the greatest degree of osseous disorganization, displacement and destruction. We may enlarge the wound, possibly effect a reduction, remove all foreign material, embalm the parts and apply supports.

In very serious cases, involving complete destruction at and beyond the site of injury, our aim will be to institute rigorous asepsis and place the mutilated member in such a position as will prevent the needless sacrifice of tissue after the line of demarkation is formed.

In many open fractures, replacement may be easily effected, there may be but little shattering; with these, the less the fragments are manipulated, the better. Bone substance though dense and hard is exquisitely sensitive to the irritation of the atmosphere, to strong chemical solutions or rough handling. Were the bone substance as immune to irritation as the peritoneum, surgery might readily remedy nearly every description of deformity.

The tolerance of bone substance has a definite limit, which when imposed on, resents it by arrest of repair or by necrosis. For this reason, it is obvious that at the time of primary examination, if constitutional and local conditions warrant it, we should institute and complete such simple osteoplastic measures as will favor the transformation of an open into a closed, or simple fracture, with early solid union. Facilities within our reach render this possible at present in the greater number of cases.

Osteoplasty in Infancy and Childhood.—It was my privilege, at a meeting of the American Medical Association, in Atlanta, Ga., in 1896, to submit an essay on the "Special Characters of Fracture in Children and in Early Life."

Every one knows that not only are the anatomical structures of the child widely unlike those of the adult, but that the finer histological elements of the osseous structures are characteristic. The skeleton in childhood is immature, elastic and highly vascular; its evolution is incomplete and hence, when damaged in varying degrees, is capable of the dual property of repair and continued growth at the same time. Nay more, sections of the skeleton in the child are capable of quite complete reproduction, after loss by injury or disease. Moreover, through compensatory agencies, many osseous blemishes and deformities are capable of obliteration during the growth of the body.

When, therefore, in serious fracture, the brunt of violence has fallen on the bone elements and the vital structures of the soft parts have escaped, conservative surgery may accomplish remarkable results. But, the limbs or the appendages of the child are tender, softer and much less resistant to compressed force than the adult's. This we will sometimes unhappily see demonstrated in those disastrous results, from the too firm splinting or tight bandaging after fracture. We will observe it also after such violence as might be safely sustained by the adult limb. The parts after the crush in open fracture of early childhood may readily perish, fail to react, and gangrene may set in early. This applies, it is true, only to extreme cases, but it is more frequent than in the adult from the same degree of force. Besides, the child bears deep shock badly, and mortal symptoms may set in early after the free loss of blood.

In the child, primary osteoplasty may be quite out of the question; but we should not despair or give up hope, unless the limb has been quite entirely destroyed at the time of injury. Hemorrhage must be immediately subdued, the parts swathed, and the little patient resuscitated; then, provided only the circulatory currents become reestablished, we may look for quite complete osseous regeneration.

In the technic of osteoplastic operations on the child, the greatest caution must be observed to preserve every particle of the periosteum possible, for however complex, the process of osteogenic repair may be with the adult, there is abundant evidence that the presence of this membrane is indispensable to osseous regeneration in early life.

Osteosection in childhood, using the heads as an osteoclast, very frequently serves a useful purpose, in strumous or rickety patients in whom union of the fragments is slow or imperfect. In these cases, when the lower limb is involved, the defective callus yields under the weight of the body after locomotion has begun, with a resulting deflection, bowing and shortening of the limb.

MEDICAL PROGRESS.

SURGERY.

Müller's Operation for Spina Ventosa.—Spina ventosa was formerly considered one of the most intractable of the minor surgical complaints and failures were numerous before Müller published his new operation. Briefly this consists in removing the diseased diaphysis with or without periosteum, sponging out the cavity with iodoform solution and then implanting a piece of the ulna with its periosteum, ½ cm. (⅕ inch) broad and 2 to 3 mm. (1/12 inch) thick. It should be long enough to fit accurately into the space between the intact epiphyses. O. Ehrhardt (Münch. med. Woch., Sept. 29, 1903) has tried this method in six cases and finds it extremely simple and efficient. If there is danger of weakening the ulna, the tibia may be employed instead. The after-treatment generally lasts three weeks, though splints must be worn somewhat longer. The presence of fistulæ is no contra-indication but cases of cicatricial shortening are generally unsuitable. The same applies to cases where the epiphyses and joint are already involved.

Aneurism Treated by Matas' Method.—In view of the fact that the German and other European writers

have to date practically neglected to recognize the existence of this admirable American technic, it is of import to note that the method is gradually gaining a foothold. The method is based upon the fact that the endothelial surface of the artery is capable of exhibiting all of the reparative and regenerative reactions which characterize endothelial surfaces in general when subjected to irritation. ROBERT T. MORRIS (Ann. of Surg., Oct., 1903) records a case of fusiform aneurism in the popliteal region, which he successfully treated by this technic. The patient was a strong, robust man, fifty-eight years of age, who had been in the habit of sitting with the right leg over the arm of his chair. No other part of his history had any bearing on the case. Swelling had appeared in the last three or four years in the popliteal region, which had been increased until at the time of the operation the aneurism was so large that its pulsations were visible on both sides of the knee when viewed from the patellar side. The edema had been so severe that the leg had to be tapped in order to allow it to subside; but despite this, the lymphatic tension was very high. This made ligation of the femoral peculiarly dangerous, and was the chief factor in causing the use of the Matas method. The part was prepared with a germicidal depilatory a few minutes before the operation. This method avoids the need of shaving and simplifies the process of establishing asepsis. The incision was 10 inches long and was carried longitudinally through the wall of the sac of the aneurism. A double handful of clots was removed from the sac, and the aneurism shown to be fusiform with a large, thin-walled diverticulum, which constituted the chief part of the mass. A running suture was passed through the deepest part of the sac so as to construct something more than three inches of a new artery of a caliber estimated to be similar to that of the popliteal, and a second row was introduced for purposes of strength. The elastic bandage was next removed and immediately the new artery began to beat. There was no leakage. The patient's foot was warm, but there was no pulsation in the arteries to be felt on account of the edema. The wound was closed without drainage and it healed completely by primary union. The anesthesia and loss of power which had been present, shortly disappeared, sensation being well defined by the seventh day. On the twenty-second day at the site of the aneurism the newly constructed artery could be felt. The restoration of function was satisfactory.

Irrigation of Biliary Passages.—F. KUHN (Münch. med. Woch., Sept. 29, 1903) warmly recommends injecting water under moderate pressure through the biliary passages at every operation for cholelithiasis. Besides ascertaining that the passages are free, one can by the addition of suitable drugs, directly medicate the diseased mucous membrane, force out mucus and small stones and exert a beneficial massage upon the tissues. The method is not risky, yet sometimes moderate attacks of colic will follow. If a pressure corresponding to 500 mm. of water is used, 25 c.c. per half minute, indicates an obstruction; 25 to 50 c.c. is normal and 50 to 100 c.c. signifies dilatation. Large stones wedged in the common duct will not be influenced but smaller calculi and sand will be expelled as effectually as after an attack of colic. All cases should be irrigated systematically after operation, to avoid recurrence.

Acute Inflammation of the Cecum.—Among 350 cases operated for appendicitis, D. REISINGER (Münch. med. Woch., Oct. 6, 1903) found the appendix normal in two though all typical symptoms had been present. They must be looked upon as instances of primary, gangrenous typhlitis, the existence of which some authors are inclined to doubt. Constipation played a prominent part in only one but it is probably the most important factor in setting up ulceration and gangrene in the cecum. The relatively little movable ascending colon will push up and compress the transverse portion so that overdistention and anemia will follow. This will naturally be most marked in the cecum where the walls are thinner and less resistant. As the feces are converted into scybalous masses, direct irritation and injury of the mucosa results. The posterior wall is especially endangered since free from peritoneum. The correct diagnosis can only be made at operation since typhlitis and epityphlitis are clinically alike.

Surgical Treatment of Lung Abscess.—Pulmonary surgery has advanced very rapidly owing to the fact that so many lung affections are not improved by internal treatment and since the tolerance of the lung toward knife and cautery is really very great. The number of successful operations in apparently hopeless cases has been large, but the celebrated specialist in lung-surgery, KAREWSKI (Münch. med. Woch., Sept. 29, and Oct. 6, 1903) warns against taking too enthusiastic a view. In the case of abscess especially, it is absolutely necessary to localize accurately the lesion and also to take its etiology into consideration for a number of forms are not suited for operative procedure. Then also, a large number of abscesses heal spontaneously and this applies especially to the metapneumonic form. Though but few lobar pneumonias are followed by abscess, the author found that 5 out of 14 were preceded by a true pneumonia. Abscesses secondary to influenza pneumonia are unsatisfactory both from a medical and surgical point of view and rarely heal spontaneously, since there are generally multiple foci which do not communicate with a bronchus, so that the pus cannot be coughed up. Should it be possible to convert all the small cavities into a large one during operation, the outlook is more favorable, though it may take a year before suppuration ceases. The chronic lung abscess of advanced age will hardly ever call for operation. Foreign body abscesses generally have thickened walls and lead to bronchiectasiæ. Every attempt should be made to remove the foreign body through the bronchi since it can rarely be found at operation and the prognosis in general is not good. Abscesses of this kind have been known to heal spontaneously where the foreign body was expectorated after ten years. The prognosis is also very unfavorable where septic emboli are the cause. A much more favorable outcome can be expected where there is an arrosion of the lung from suppuration in the neighborhood. Perforating hepatic and subphrenic abscesses and cold abscesses secondary to Pott's disease are the most frequent source of this class, while in a few cases softened bronchial glands, gastric ulcer, strumitis with mediastinitis and perinephritis were found. These conditions often run as obscure, chronic sepses until the pus breaks into the lungs, when the patient's condition will suddenly improve. A single, well-circumscribed focus is generally found in the lungs at operation. In all cases in which the pus is not freely evacuated through the bronchi, it is wrong to wait for a spontaneous perforation, since chronic sepsis, brain abscess or recurrent joint inflammation may follow. Before deciding upon an operation, it is important to ascertain if acute or chronic. In the latter, there are often multiple foci with dense, unyielding walls which greatly prolong the process of granulation. The condition of the ribs is of great importance; the ribs of young individuals are more elastic and flexible and readily adapt themselves to changed conditions within the lungs. An apical abscess heals more readily than a basal one since drainage is more perfect both by way of the bronchi and the drainage tube. Since,

however, the lower lobes are more movable, the contents will be more readily expelled and the surrounding organs will tend to fill in the defect and thus hasten cicatrization more readily in this locality. In general, an expectant treatment is admissible in young individuals, with small apical foci or with larger, recent, basal foci. In many cases the abscess tends to progress toward the surface of the lung and many an empyema has been operated and its cause, a lung abscess, detected only later during the after-treatment. Operation should not be deferred until an empyema sets in, since this renders the prognosis much worse. It is not necessary to wait until pleural adhesions have formed; if the operation is conducted in two stages and the lung sutured to the costal pleura with silk saturated in turpentine, during the first act, the surgeon need not fear that he will be the cause of an empyema. A great advantage of early operation lies in the fact that the patients are improved permanently, whereas with internal treatment a recurrence may follow, even after years of latency.

PHYSIOLOGY.

New Researches on Indicanuria.—It has been observed that during the oxidation of indoxyl, there are produced not only indigo-blue, but also red and brown substances. The reseaches of C. Porcher and C. Hervieux (Hoppe-Seyler's Zeitsch., July 31, 1903) show that the rapid oxidation results in indigo-blue, while the slow oxidation results in indigo-red. The authors obtained a positive indigo-reaction in the cases of the urines of horses, dogs, rabbits, guinea-pigs, and also human beings. In their opinion indican is a normal constituent of urine and consequently indicanuria loses in significance as a diagnostic sign.

The Relative Toxicity of Distilled Water, Sugar Solutions, etc., for Marine Organisms.—One need not discuss the possible practical interest or profit which medical science may have in the investigations on the above theme by Jacques Loeb (Pflüger's Archiv, July 8, 1903). He found that for a certain species of *Gammarus*, distilled water and a solution of sugar is osmotic with sea water are about equally toxic. In both solutions at the warm temperature the organisms die in half an hour. Hypotonic sugar solutions are not as poisonous as the above. Pure solutions of table-salt that are isosmotic with or less concentrated than sea-water, have the same effect as distilled water. The organisms die sooner in a solution containing all the constituents of sea-water except sodium chloride, than if kept in distilled water. If a solution be used in which NaCl, KCl and $CaCl_2$ are present in the same concentration in which Na, Ca and K are contained in sea-water, *Gammarus* will live for several days. The addition or $MgCl_2$ will prolong the life of the organism, but the addition of the other constituents of the sea-water will have no effect in this respect. From these facts it follows that the sodium chloride contained in sea-water is by itself poisonous and that this toxicity is neutralized by the Ca—and K—salts, and that the K— and Ca—ions contained in sea-water are by themselves more poisonous than the NaCl, but their toxicity is abolished by the presence of the NaCl. The reciprocal neutralization of these toxic actions requires that the concentration of the antagonistically acting salts or their ions should bear a definite relation to one another, corresponding to the normal relationship in sea-water. These facts corroborate the results already obtained by Loeb, in showing that sea-water with respect to its contained organisms (and the serum of an animal with respect to the tissues which it bathes) furnish a solution of salts which is in physiological equilibrium, in which the toxic actions mutually antagonize one another. If the concentration of certain constituents be altered within certain narrow limits, it is possible to impart to the tissues properties which they do not possess normally, as the author has shown in his experiments on artificial parthenogenesis, the rhythmical contractions of muscle and the increase in the excitability of muscle and nerve. The author is convinced that this theme is pregnant with suggestions for the science of pathology in general, and for that of nervous diseases in particular. The researches furthermore strengthen the hypothesis that the toxicity of distilled water and other substances depends upon the fact that electrolytes leave the organism. It is probable that antagonistic salts or ions do not leave with equal rapidity or in the same relationship. Such a disturbance of the relation of the concentrations of antagonistic salts or ions in the tissues, would hasten the onset of death.

Resuscitation of the Heart.—A number of interesting experiments of A. Velich (Münch. med. Woch., Aug. 18, 1903) prove that the heart can be made to contract many hours after the death of the animal, provided an artificial circulation of some nutritive solution be kept up in the cardiac muscle itself. Thus, a young dog was killed, the heart removed immediately, placed in physiological salt solution, and exposed to a low degree of temperature. Twenty-four hours later, a fluid containing sodium, calcium and potassium chloride, bicarbonate of soda and 0.1 per cent. glucose, was allowed to circulate in the coronary vessels. After several minutes, both auricles began to pulsate distinctly and soon the ventricles also showed feeble contractions. In another experiment a dog was killed by means of nicotine. Ten minutes after the heart had stopped beating, 200 c.cm. of the above-mentioned fluid were injected into the heart in a centripetal direction. A closure of the aortic semilunar valves was affected and the fluid was forced into the coronary arteries and left the heart muscle again by way of the coronary veins. Contractions soon appeared and in a few minutes the entire circulation was restored and the animal revived. The writer believes that this method can be applied with success in medicine, in cases of sudden cardiac collapse.

Action of Bile on the Heart.—The clinical observation has been made that during the course of an acute icterus, the heart action shows marked disturbances, among which the slowing of the pulse is the most noteworthy. In order to explain this phenomenon K. Brandenburg (Berl. klin. Woch., 1903, No. 38) has lately made some animal experiments which go to show that if bile is introduced in small quantities into the circulation, reflex excitation of the vagus is produced by the irritation of the sensory nerves of the heart. This leads to a transitory weakening of the auricular contractions and a slowing of the heart beats. It is only after the introduction of larger quantities of bile that the heart muscle itself is damaged. The long continued action of blood containing bile affects the muscle cells very slowly and first involves those which lie near the openings of the large veins of the heart. The action of the bile on the heart depends on the presence of biliary acid salts, but as these are sparingly produced in chronic icterus, the absence of a slower pulse rate may be thus explained in the latter class of cases. The slowing of the pulse rate in many acute cases of icterus is therefore to be considered a very complex phenomenon, brought about by the combined action of the biliary salts producing in the first place a reflex stimulation of the vagus and in the second a destructive change in the heart muscle cells near the openings of the large cardiac veins.

The Alexins in Recurrent Fever.—It is only recently that the part played by alexins in convalescence

from infectious disease became well understood, and the estimation of the amount of this so-called protective proteid in the various conditions where it is encountered has been engaging the attention of several investigators of late. A. A. MELKICH and J V. KALYAPIN (Roussky Vrach, No. 35, 1903), present a résumé of conclusions touching this subject, as drawn by Housseff, at the bacteriological institute at the Kasan University, according to which the quantity of alexins in the serum of healthy individuals is more or less constant, while their variation in diseased states depends entirely on the pathogenic principle of the given disease. At the height of infection that terminates favorably the amount of alexins is above normal, while this amount falls considerably at the moment of intense struggle between the force of the organism and the infectious principle; there seems to be no relation between the amount of alexins and that of the white blood corpuscles, or their several varieties. The authors base their results on investigations of 14 cases of recurrent fever, in whom there were made daily examinations of the amount of alexins, and the hemolytic power of the serum. They find that the alexin indicator is very high (5.62; 4.82; 5.83;) during the first attack, and diminishes gradually up to the last day (2.84), while during apyrexia the fall comes down to 0.27, but rises rapidly again in two or three days; a considerable fall is also observed on the eve of the crisis. Then the indicator rises at the period of convalescence to 5.06 and keeps at that height up to the time the patient is discharged. As regards the natural hemolysis it seems in a general way to run parallel to the alexin curve, with slight deviation at times. The variations in the alexin curves show decidedly a rise during the beginning of the attacks and a fall at the time of the crisis. During the first apyrexia the curve rises again up to the normal or even above it, and this rise continues for several days. Just before the second attack the curve again approaches the normal, falls after the second crisis, rises rapidly at the period of convalescence and stays so until complete recovery. These results, based as mentioned above on the investigations of recurrent fever, coincide completely with the investigations made by the former investigator on malaria and catarrhal pneumonia. It is unfortunate that the complexity of the investigations, as well as of the calculations, prevented the authors from establishing the number of white corpuscles and similar bodies in the blood, as this would greatly assist us in solving the problem of the origin of the alexins; it would, however, interfere with the investigations concerning the hemolytic and bactericidal properties of serum. Dr. Melkich has, however, in one of his former works, elaborated some conclusions on this subject, and he finds (1) that during the attack the number of white blood corpuscles increases quite rapidly, and this increase reaches its highest a day before the crisis; (2) this increase may last for one or two days, then it gives way to a rapid diminution in the general number of the white blood corpuscles, and every following crisis is accompanied by a more pronounced and rapid hypoleucocytosis. The lymph corpuscles participate but very little in the general increase of the white blood corpuscles, and their curve does not correspond to the curve of the multinuclear cells, nor is it in any way related to the variations in leucocytosis.

Increased Heat Production as a Cause of Fever.—In cases of cerebral hemorrhage in the neighborhood of the corpus striatum there is frequently a rise of temperature and if the temperature of both axillæ is measured a higher record is often obtained on the paralyzed side. In two cases of ordinary hemiplegia, W. HALE WHITE (Zeitsch. f. klin. Med., Vol 50, Nos. 3 and 4) also found the temperature higher in the axilla of the diseased side. In one, the surface temperature was alike on both sides, but the perspiration secreted on the paralyzed side was much higher, so that heat dissipation must have been much more rapid here. Since, however, the internal temperature was increased, it follows that more heat was actually liberated. In typhoid and suppuration the fever is chiefly due to a diminished dissipation of heat, in pneumonia and erysipelas more to an increased production like in hemiplegia.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Bilharzia Disease.—Tropical medicine has come to be of ultra importance to us in the last few years because of territorial expansion. S. R. DOUGLAS and F. W. HARDY (Lancet, Oct. 10, 1903) reached the following conclusions from a study of 50 cases of this disease: The histological characters of the blood exhibit the following changes: (*a*) The percentage of the coarse-grained eosinophile leucocytes is, with very few exceptions, much above the average found in normal blood. This increase is proportionate in the diminution of the polymorphonuclear leucocytes. (*b*) Less frequent is an increase of the large mononuclear leucocytes, and where this is present, it is associated with a diminution of the lymphocytes. The histological characters of the leucocytes in the urinary sediment are as follows: They are almost exclusively coarse-grained eosinophiles, the large mononuclear form being very uncommon. The ova in the urine vary in number from day to day. Large quantities of blood and other cells are often present when but few ova can be found.

Healing Tendency in Nephritis.—After examining the kidneys of rabbits a varying length of time after they had received sufficient bichromate of potassium, to set up an acute nephritis, Ch. THOREL (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 1 to 6) concludes that a healing tendency manifesting itself in cell-division and regeneration of lost epithelial cells shows itself very early at a time when parenchymatous degeneration is still progressive. The kidney possesses the property to replace lost tissue with functionating glandular structures, to a very high degree and the frequency with which acute and subacute nephritis is cured, must be ascribed to this. Where, however, the intoxication continues, all regeneration will be useless since the newformed cells will rapidly undergo necrosis.

A New Culture Medium for Tubercle Bacilli.—W. HESSE (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 5 and 6) prepares a nutrient agar by boiling 10 gms. of agar, 20 to 25 c.c. of glycerin and 1,000 c.c. of distilled water for one-half to one hour and then filtering. 25 c.c. are then filled into each test-tube and sterilized one hour in live steam on three succeeding days. For each sputum to be examined, six tubes are used and these are rendered alkaline with 0 0, 2 0, 5 1, 2 and 5 c.c. of decinormal potash solution respectively before being poured into Petri dishes. The object of this is to obtain a medium of the same alkalinity as the sputum to be examined. The patient is directed to remove all saliva from the mouth and then to cough the sputum from the deeper parts into a sterile dish. Several small particles are deposited upon the inverted surface of an agar plate and carefully distributed. The sputum is thus isolated into a number of small flakes and a sterile cover-slip is loosely placed over one of these. The dish is then encircled by means of a rubber band and placed in the incubator. The material necessary for the growth of the bacilli is contained both in the sputum and in the culture medium. After 1 to 3 days the germs will have multiplied upon that medium whose alkalescence

corresponds with that of the sputum, and it is only necessary to remove the cover-slip and stain with carbol-fuchsine. After one to two weeks the colonies will be visible with low magnification. Hesse believes that the alkalinity of the mucus in the bronchi plays an important part in infection. If a catarrhal condition of the air-passages exists and tubercle bacilli are inhaled a general infection is less liable to occur, if the reaction of the mucus differs materially from that of the former culture medium of the germs, since their propagation will here be slow and the organism will have time to protect itself against their invasion. Where, however, the reaction is the same, a generalization of the infection is more apt to occur. Bovine mucus is much more alkaline than human, hence the bacilli from cattle can only cause local lesions in man and conversely.

Differential Leucocyte Count in Early Days of Typhoid.—The value of a differential count of the leucocytes during the first week of the disease has generally been thought to be of doubtful importance for the relative changes peculiar to typhoid were believed to begin during the second week and gradually progress during the third and fourth. H. A. Higley (Med. Rec., Sept. 19, 1903) has carefully counted the leucocytes in a number of cases within the first week of what was subsequently proven by various clinical and bacteriological tests to be typhoid fever. In order to determine the day of the disease, considerable reliance was placed upon the time of the appearance of the eruption, which was frequently and faithfully examined for. The time when it first appears is given differently by various authorities, but it is pretty generally agreed that it should appear from the seventh to the tenth day of the disease. In each of his cases the leucocyte count was taken at least three days before the appearance of this rash and, therefore, the case could safely be said to be within the first week. The average percentages for the various leucocytes were: small mononuclears, 17.8 per cent.; large mononuclears, 21.1 per cent.; polymorphonuclear neutrophiles, 59.4 per cent.; eosinophiles, 1.7 per cent. Such an increase of large mononuclears in the early stages of the disease would naturally be of considerable assistance in making a differential diagnosis. There is, however, always an important personal element in distinguishing the small from the large mononuclears, and it should be said that in these results reported above all those mononuclear non-granular leucocytes which were larger than a red blood cell (Jenner stain) were counted as large mononuclears.

Behavior of Typhoid Bacilli in Milk.—From the results of a large number of practical experiments and culture tests, R. Bassenge (Deut. med. Woch., Sept. 24, 1903) finds that heating milk to 60° C. for five minutes is sufficient to destroy whatever typhoid bacilli may be present. For this purpose earthenware vessels are preferable to those made of iron or enamel ware. The destruction of bacilli in raw milk is favored by the formation of acids, such as lactic, butyric, etc., when the acidity becomes greater than 0.3 to 0.4 per cent. and has been present for over twenty-four hours. In buttermilk, whey and butter, the bacilli perish under the same conditions. During the process of centrifuging milk for making butter, the bacilli largely find their way into the cream and may remain there in an active state until the condition of acidity already mentioned arises. This corresponds, however, to the period when the taste of the butter becomes affected, and before this time, that is, when the butter is more apt to be eaten, the bacilli are still present in their original virulence.

Morphological Biology of the Tubercle Bacillus in Unfavorable Media.—The changes which the bacillus tuberculosis undergoes in media unfavorable to its development have been carefully studied by G. Guyot (Gazz. Osped., Sept. 20, 1903). Naturally, the greatest interest centers in the variations seen in the organism under the influence of antituberculous serum. These the author describes as follows: The bacillus first swells, stains feebly, and as it increases in length and breadth the coloration becomes paler and irregular. Then follows fragmentation of the body, so that it seems to be divided into two or three parts of normal color united by almost colorless segments. From the junction of two or three of such bacilli a chain is formed which is not unlike the streptococcic chain in appearance. Ultimately the fragments of the bacilli become isolated and assume a great variety of shapes. In addition to the chain-like formation of the bacilli, agglutinated amorphous masses of the organism are seen. The author calls especial attention to the small round or oval bodies seen by him when the bacilli were in advanced stages of degeneration. These are generally seen at the extremity of a bacillus; but one being associated with a single organism, as a rule. They stain very intensely and are most abundant in specimens subjected to the influence of antituberculous serum for two weeks or more. The writer thinks it not improbable that these bodies may be spores.

Diminishing the Virulency of Tubercle Bacilli.—The results of extensive experiments by H. Herzog (Centralbl. f. Bakt., Oct. 9, 1903) demonstrate without a doubt that tubercle bacilli, inoculated into cold-blooded animals, will remain virulent for over 190 days. If, however, the germs are again used for inoculating guinea-pigs these animals will remain alive a much longer time, which is not due to a diminution of the number of germs in the cold-blooded organism, since they readily multiply here, but to a direct reduction of virulency. By inoculating a second and a third series of frogs with germs which had already passed through a frog, an increased susceptibility of these animals is noted, showing a marked power of adaptability on part of the bacillus. Morphologically it will more closely resemble the germ of fish tuberculosis and guinea-pigs do not so readily succumb to inoculation. The maximum temperature of growth is also considerably lower. The same observations were observed when the germ of bovine tuberculosis was substituted for that of human tuberculosis in all the experiments, which seems to show that they are at least closely allied.

Behavior of Blood at Different Ages.—Certain animal poisons, as spider toxin, behave differently with the blood of different species: with some animals hemolysis is rapid and complete while with others, no effect is produced, since a sufficiently large number of receptors are circulating in the blood. That these receptors may only be lost, as the animal gets older, is shown by H. Sachs (Centralbl. f. Bakt., Oct. 9, 1903). Newly born chicks possess a complete immunity toward spider-toxin, while in the full-developed animal the poison rapidly proves fatal. An increased resistance in general is not, however, present, for other poisons, such as staphylolysin is more toxic for young animals than for old. Fetal bovine blood is very susceptible toward cobra-poison, but becomes more resistant as the animal grows and the phenomenon here stands in close relation to the degree with which the lecithin is combined with the red cells.

Agglutination of Streptococci.—Streptococci obtained from the blood of scarlet-fever patients and grown for some time upon artificial culture media are specifically agglutinated in the great majority of cases by an immune serum obtained from these streptococci, according to P. Moser and C. P. v. Pirquet (Centralbl.

f. Bakt., Oct. 9, 1903). The phenomenon is typical both microscopically and macroscopically. Attempts at serodiagnosis, similar to the Widal reaction, were then made, with partial success. Distinct agglutination was obtained in scarlet fever in 54 per cent.; in other affections in only 11 per cent. The more severe cases of scarlet fever give agglutination more readily. Distinct clumping was also obtained in meningitis, perityphlitis and with placental serum, but never in the dilution of one to eight.

Anatomical Lesions after Ingestion of Organic Extracts.—There are very many articles in literature upon the physiological action of the various organic extracts but hardly any upon the lesions they produce when injected. In a preliminary report, G. GHEDINI (Centralbl. f. Bakt., Oct. 9, 1903) records some results he obtained with pancreas, thyroid, thymus, brain, testicle, ovary and suprarenal gland. The axillary and inguinal lymph-nodes were found much swollen, liver, kidneys and spleen were in an inflamed condition with infiltration, degeneration and vessel changes and the thyroid was hyperfunctionating. Other organs, even if they corresponded to the organ injected, showed no change. Probably the lesions are a result of the liberated nucleoproteids which act as non-specific toxins. This would explain why organs which normally free the body from poisons are most particularly altered.

Meningococcus in the Nose.—It is well known that pneumococci are frequently found both in nose and mouth of individuals not suffering from pneumonia, and the article of F. T. LORD (Centralbl. f. Bakt., Oct. 9, 1903) proves that the meningococcus may occur in the same secretions without meningitis. Organisms present in the nose and resembling this diplococcus in morphology and staining reaction cannot be accepted as meningococci unless the diagnosis is confirmed by cultures, in view of the close resemblance which exists between the meningococcus, gonococcus, pneumococcus and *Micrococcus catharrhalis*. In Lord's patient the process began as an ordinary coryza with lacrimation, headache and prostration. The nasal secretion, at first watery, became purulent in a few days With more abundant discharge, the general symptoms did not abate and it took over three weeks before the patient was again able to work.

Cause of Ekiri.—In the dejections of patients suffering from ekiri, a peculiar form of dysentery of Japan, S. ITO (Centralbl. f. Bakt., Oct. 9, 1903) discovered a pathogenic bacillus which morphologically resembled the colon bacillus. It was decolorized by Gram, possessed more active motility than the colon bacillus, did not fluidify gelatin, generated gas in the presence of glucose, did not coagulate milk and was further marked by a much delayed indol reaction. This germ was never found in the feces of healthy individuals. By adding blood-serum of patients who had recovered, a distinct agglutination took place but the serum of healthy individuals or of those who had suffered from dysentery, acute enterocolitis with fever and allied diseases had no effect. The blood-serum of recovered patients did not cause clumping of the dysentery, typhoid or colon germs. The absolutely specific character of the bacillus could also be demonstrated by inoculating animals.

Studies upon Smallpox. In the blood removed aseptically from the heart of patients who had died of smallpox H. DE WAELE and E. SUGG (Arch. Internat. de Pharmacodyn. et de Therap., Vol. 12, fasc. III and IV) discovered the streptococcus in pure culture. Their number varied with the stage of the disease and was greatest with the papular and papulovesicular stage. During life they could also be found in the blood withdrawn as well as in the vesicular eruptions. This streptococcus was agglutinated by the blood of all patients suffering from variola, and conversely the serum agglutinated any of the streptococci isolated from other cases of smallpox, but not other streptococci except such which were specific for diseases which the patient had passed through. The serum of every vaccinated individual also agglutinated this streptococcus but less so than after an attack of the disease. The serum of non-vaccinated individuals or of newly born infants possessed no agglutinating power; this developed only and increased during the course of the disease. The various antistreptococcic sera on the market did not agglutinate the variola germ but with the serous exudate of the vesicles, distinct clumping could be obtained. The germs were also abundant in the crusts and in the air of the wards and sick-rooms. It is probable that it gains entrance into the system by the respiratory passages and in two-thirds of the cases the disease begins as an angina with infectious secretion. This angina is simultaneous with the first rise in temperature. The streptococci then pass into the blood and are arrested in the skin (papular stage), where they proliferate (vesicular stage and second rise of temperature). This peripheric infection is followed by an invasion of leucocytes (pustular stage) and as the epidermis separates under the lesion, the pustules dry out and become converted into crusts. One can also find the streptococcus in postvariolous abscesses and a postvariolous septicemia may be due to this germ which, however, undergoes changes which tend to alter its characteristic properties and which can be demonstrated by animal experiments. A streptococcus can be isolated from the various vaccine viruses which present the identical properties. It is not agglutinated except by the serum of vaccinated or variolous subjects. The addition of glycerine to the virus, especially when this is old, makes it difficult to demonstrate the organism by simple culture. The plurality of streptococci is rendered certain by the discovery of the germ of smallpox and it may soon be possible to separate it into distinct groups. An efficient serum diagnosis and serumtherapy is promised in the near future.

The Influence of Potassium Sodium Tartrate on the Circulation.—A contribution to the knowledge of this subject is made by F. KLEEBERG (Am. Med., Oct. 17, 1903), who employed dogs for his experiments. In each case the animal was given 0.02 gm. (¼ gr.) of morphine sulphate before beginning the administration of ether. The canula was invariably introduced into the carotid artery for determining the blood pressure, and the salt was injected into one of the crural veins. In the author's estimation these experiments prove that potassium sodium tartrate, when injected intravenously in small amounts (up to 30 mg. per kilogram of dog), causes a fall in the blood pressure and an irregularity in the rhythm of the heart's action. This may be accompanied by a primary slowing of the heart's beat, but the dominant action is to cause an increase in the rate of pulsation. The fall in pressure occurs even though the quantity of salt injected contains less than 3 mg. of potassium per kilogram of dog. If the amount introduced is larger and yet insufficient to cause complete paralysis of the heart, the fall of blood pressure is accompanied by a slowing of the heart. If the salt is introduced in comparatively large quantities, the animal quickly expires, owing to paralysis of the heart, respiration continuing for some moments after the heart has been arrested in diastole. It was also found that neutral sodium tartrate, when introduced intravenously in moderate amounts (about 50 mg. per kilogram), stimulates the heart, causing a rise in blood pressure with a slight increase in heart rate. He believes that

the depressing factor is the potassium ion, and that the sodium and tartaric acid ions are without influence in causing the depression.

The Physiology and Pharmacology of Silicic Acid.—It has been generally believed that silicic acid is a comparatively unimportant substance from the standpoint indicated. H. Schulz (Deut. med. Woch., Sept. 17, 1903) has found that the administration of the acid in the human subject was not followed by any effects on the respiratory or vascular systems, but that small amounts caused marked derangement of the nervous system, including headaches, vertigo, somnolence, with an inability to concentrate the attention, nervousness and irritability, uncertainty in gait and tremor of the hands. Cutaneous effects consisted of an eruption of acne pustules or papules, and also hyperidrosis, with an acid perspiration and desquamation. The hair manifested a tendency to drop out and the nails to grow faster. The digestive disturbances consisted of flatulence and colic, alternating constipation and diarrhea. In both man and animals the stools were remarkably yellow. Diuresis was not noted unless the acid had been taken a long time. In some cases polyuria developed with smarting pain on urination, while in others there was retention, the urine being concentrated and of a red color, until diuresis had become established. The patients complained of a feeling of weight in the legs and were easily fatigued. Pains in the tibiæ were also noted and the joints were stiff and ached, suggesting the symptoms of lead poisoning.

Hernia Inherited from Mother's Side and Polydactylism from Father's.—An interesting report is presented by B. K. Bauer (Prak. Vrach, Sept. 20, 1903) touching upon a male child, one year old, in whom the author discovered a right inguinal hernia the size of a goose egg, which the mother observed when the infant was four weeks old. The small fingers of the child's hand show traces of supernumerary members which had been severed soon after birth. The middle and ring fingers are grown together by the aid of an intervening membrane, while the large toes are so wide as to give the impression that they were made up of two, and the appearance of the double nail lends the more credit to this belief; the middle and second toes are grown together up to the phalangeal joint; but the toes in general are quite movable. The boy's brother, a child of two, has a left inguinal hernia, which also appeared for the first time when he was but one month old. A membrane unites the middle and ring fingers of both hands, but the fingers are fully developed. The toes are just as large and wide as those of the other child. The last toes of either foot have marked supernumerary members. According to the mother's statement neither she nor her husband ever had hernia, while her father is at present suffering from hernia, which made its first appearance during the first month of his life, two of her uncles also have hernia, which were noticed at the same age as in her grandfather; a similar state of affairs is seen in four of her cousins, so that in general it may be said that the family on the mother's side shows a predisposition toward inherited hernia. A similar predisposition as regards polydactylism is noticed in the family on the father's side, thus: The father himself has six fingers on either hand; the middle and ring fingers of the left hand are grown together, the toes are large and wide; the same abnormalities are seen in his father—that is, the children's grandfather, whose father in his turn presented a similar appearance. It was impossible to elicit any more positive history as to similar abnormalities in other branches of the families. Both children were operated on for hernia and syndactilia successfully.

NEUROLOGY AND PSYCHIATRY.

The Nature of Inhibitory Processes within the Nervous System.—A review of the current theories on inhibition, a new hypothesis as to the nature of this phenomenon in the nervous system and an experimental support for the same, are discussed by W. McDougall (Brain, Summer, 1903). The first theory as to the significance of inhibition was put forth by Hering, who in holding that protoplasm is the seat of two simultaneous antagonistic processes, namely, anabolism and catabolism or assimilation and dissimilation, suggested that inhibition would correspond to the latter. According to Gaskell, who worked out independently a similar theory, increased anabolism tends to inhibit the vital manifestations, the effects of catabolism, only by checking the rate of catabolism. The view taken by Mercier, in his paper on "Inhibition," is that this phenomenon consists in the blocking of the paths of discharge of "nerve centers," the resistance of such paths being raised above the normal in some way. A view long ago proposed by Wolkmann was that inhibition is a process of interference of waves of nervous action in a manner analogous to the interference of sound and light waves. According to the author, inhibition in the greater part of the nervous system, all the part concerned in the control of the skeletal musculature, consists simply in the cutting off from the tract inhibited of the excitatory impulses by which alone its activity can be maintained. The principle of psychology, that the mind can attend to only one object at one moment of time, lends support to the view that the inhibition of a mental process is always the result of the setting in of some other mental process, or, in other words, that inhibition appears always as the negative or complementary result of a process of increased excitation in some other part. Inhibition may, therefore, be regarded as essentially the result of a process of competition. The phenomena of inhibition in the spinal cord and the facts of "reciprocal innervation," as established by Sherrington—namely, that when an excitatory impulse is sent along a motor nerve, an inhibitory impulse is transmitted to the spinal centers of the antagonists of the contracting muscles—all tend to support this so-called "drainage" theory of inhibition, whose significance would appear to depend upon the fact that a limited amount of vital energy is at the disposal of the nervous system, so that when this energy is sent along certain channels, it must necessarily be withdrawn from other quarters, which withdrawal would constitute the phenomenon of inhibition.

PEDIATRICS.

The Glycogenetic Function of the Child's Liver in Pertussis.—The work of Crisafi having suggested that a reflex stimulus might be sent from the central nervous system to the liver by reason of the irritation of the laryngeal end filaments of the vagus in pertussis, and produce much the same effect upon the glycogenetic function of that organ as do puncture of the fourth ventricle, lesions of the vagus, pons, etc., D. Benedetti (Riv. di Clin. Ped., September, 1903) has sought to solve the question of insufficiency of the liver's glycogenetic function in pertussis by administering to 13 children affected with that disease from 1 to 1½ ounces of levulose and testing the urine passed four hours after its ingestion. A positive reaction to phenylhydrazin showed the presence of levulosurea in 12 of the patients; and the author accounts for the negative result in the thirteenth upon the ground of a more active combustion going on in the organism in this case owing to the high temperature (103° F.). Some enlargement of the liver was apparent in all the patients. The results

of this investigation, in the author's opinion, justifies the belief that the glycogenetic function is insufficient in children suffering with pertussis.

Leucocytes in Summer Diarrhea.—The healthy infant has about 13,000 leucocytes in the cubic millimeter and the differential count shows that about 40 per cent. are polynuclears, 55 per cent. are lymphocytes and about 5 per cent. are mononuclears. J. Zahorsky (N. Y. Med. Jour., Sept. 12, 1903) has investigated the leucocytes in a large number of cases of infant diarrhea and has found that there is an increase in the number of leucocytes in nearly every case, but the increase is too variable to be of any diagnostic importance. There is, however, one change which stands out prominently, and that is the relative increase in the polymorphonuclears and the decrease in the lymphocytes. This is of importance, because it is found to be of value in prognosticating the severity of the attack. A marked increase in the number of polynuclear leucocytes means that the child is badly poisoned, whatever the other signs may indicate.

GENITO-URINARY AND SKIN DISEASES.

Acne Rosacea.—The commencing erythema of acne rosacea is a very troublesome and disfiguring complaint, especially to ladies. The local treatment is most important. H. S. Purdon (Dublin Jour. of the Med. Sciences, Sept. 1, 1903) uses an ointment containing 10 grains of the iodide of cadmium in one ounce of vaseline rubbed well into cheeks and nose at night, and washed off next morning with hot water and an overfatted soap, accompanied by massage of all the affected skin. The iodide of cadmium does not stain the skin and is an excellent local stimulant. If too strong it will irritate.

Effect of Light and Heat Rays on the Temperature of the Skin.—An interesting series of observations have been made in a series of about one thousand cases with the aid of Herz's apparatus, by E. Sommer (Berl. klin. Woch., Oct. 5, 1903). This apparatus is essentially a differential air thermometer, furnished with an alcohol manometer. Incandescent electric lights in blue, red, yellow and green globes were employed, the lamp being held about 10 cm. from the skin for a period of ten minutes. It was found that the skin over chronically inflamed joints was lower than on the healthy side, unless an acute exacerbation of the process was present, in which case the relations were reversed. Under the influence of warmth and light radiation the temperature of the side treated always rose above that of the other side; but there were certain cases noted in which the temperature after exposure to the rays was less on both sides than before. Radiation of this type does not produce a reaction in the sense of a cooling, with the same regularity as results from the application of heat and cold by other methods. The effects of the rays with a short wave length, are of longer duration than those with long wave lengths. After two or three hours the relations change, the side exposed seems colder than the other, a condition which is apparently due to the reactionary rise on the side which was not exposed

Abnormal Frequency of Urination Treated with Epidural Injections.—Where abnormally frequent urinations are due to disturbances in the bladder innervation, Fernand Cathelin, of Paris, devised the operation of epidural injections and obtained such good results that considerable work has been done recently along similar lines by F. C. Valentine and T. M. Townsend (Med. Rec., Sept. 26, 1903). The eight cases reported were all patients at the Manhattan Hospital West for the insane. They were all adult women and had histories of wetting the bed and clothing frequently for some time previously. The injections are made into the sacral canal between the periosteum of the vertebræ and the dura mater. The canal is reached through its opening in the sacrum. The patient is placed in the Sims position, the area sterilized and the small osseous tubercles just below and to either side of the last palpable sacral spinous process are made out. The needle of an aspirating syringe is then thrust through the skin drawn tightly between these two tubercles, the needle being held at an angle of 40° to the sacral curve until it passes through the membrane covering the opening of the canal when it is lowered to 20° and pushed on into the canal. Five centimeters of sterile salt solution were usually injected at first and later ten or even fifteen. These injections were made at intervals of about one week and favorable results followed immediately in all eight cases upon whom the injections were made. These cases have not been followed very long, but most promising results have thus far been obtained. The injections seem to be in nowise dangerous to the patient, and are no more painful than any hypodermic injection. The immediate effects are rarely even disagreeable. The rationale of the treatment is not fully explained and is probably not wholly understood.

OBSTETRICS AND GYNECOLOGY.

Ovariotomy During Pregnancy.—The patient entered the hospital because of a large tumor in the abdomen. On examination Baikoff (Prak. Vratch, Aug. 30, 1903) found the patient, a peasant woman, thirty years old, to be of good appearance and nutrition, but with an abdomen of such dimensions as to make any thorough examination of it almost impossible. It presented the appearance of pregnancy, palpation elicited an elastic, fluctuating tumor, its upper end toward the gastric region, the lower reaching down into the pelvis. With the patient on her back there was no diminution in the size of the tumor; percussion brought out dulness. In the lower portion of the abdomen another swelling was palpated emerging from the pelvis and rising to almost the middle between the umbilicus and the pubis; this feels like the uterus. Combined examination corroborate the above, and with the linea alba, pigmented areolæ and the condition of the vaginal walls a diagnosis of pregnancy of four months was made in addition to cystoma of the left ovary. In view of the rapid growth of the swelling, as well as of the gravid uterus, immediate operation was advised and performed. Incision was made in the median line beginning with a point two fingers above the umbilicus down to the same distance from the pubis. On opening the abdominal cavity the pregnant uterus was seen in the lower portion of the wound, while the upper was occupied by a part of the tumor beyond it. The size of the swelling necessitated puncture by a Spencer Wells trocar and the contents, a thick, gluey fluid of a dark color mixed with pus, evacuated. The emptied cyst was then brought outside and separated by cutting through its pedicle. The abdomen was then closed and aseptically bandaged. The course postoperatively was uneventful. On the fifteenth day patient began to suffer from strong uterine contractions and hemorrhage. In anticipation of an impending abortion extr. viburnum prunifol. fl. was administered, twenty drops four times a day, and in five days patient left hospital entirely recovered (no abortion having taken place). Author saw patient again in two months, when the pregnancy was continuing normally, but does not state as to the termination of same.

Gonorrhea in the Female.—A series of questions concerning some of the more interesting points relative

to gonorrheal infection in women was submitted to several distinguished gynecologists, and the answers embodied in an article in the Internat. Med. Jour. for Oct., 1903. The proportion of pus tubes secondary to gonorrhea encountered in the various practices varied from 12 to 85 per cent. Radical surgical treatment alone gives hope for cure unless the infection is limited to the urethra and Bartholinian glands, but even with extensive operation the gonococcus may remain hidden in the deeper layers of the vagina, urethra or glands. The fact that pregnancy may follow is no proof of a radical cure. Vaginitis is rarely of gonorrheal origin, except in children; in adults it only constitutes about 10 per cent. Endocervicitis is best treated by the application of tincture of iodine, argyrol 30 per cent., negative galvanism, or carbolic acid. Repeated applications can thus prevent extension in recent cases. For corporeal endometritis, topical applications are generally not admissible, unless the os is wide and drainage perfect; it is generally better to use a double-current catheter with boric acid solution or weak iodine. The opinions were divided concerning hysterectomy for pus tubes, the majority do not practice removal of the uterus and are even in favor of conservative treatment for tubes and ovaries. Microscopical examination is often the only safe way of diagnosing urethral gonorrhea. Wherever the discharge is taken from, pressure should always be made upon the parts so as to compel the compound racemose glands to discharge their deeper contents. Gonorrhea extends to the endometrium, tubes and peritoneum in about 5 per cent. of those infected, but deaths are very rare.

EYE, EAR, NOSE AND THROAT.

An Operation for the Removal of Tonsils.—When the hypertrophied tonsils are not attached to the pillars, no difficulty will be experienced usually in removing the offending organs by means of the various tonsillotomes. W. H. Steers (Med. Rec., Oct. 3, 1903) believes that in those cases where there are a number of adhesions to the pillars these instruments are unsatisfactory, as they leave a large part of the tonsil behind. In these cases he recommends the use of a knife and forceps to assist in dissecting out the tonsil. He employs a hook-like knife modeled from the lines of a strabismus hook, making the handle longer and stouter and giving a knife edge to the concavity and end of the hook. The tonsil being well exposed by mouth gag and tongue depressor, the tonsil is seized by a Kelly volsellum and drawn toward the opposite side. The hook-knife is then passed between the tonsil and the anterior pillar, taking care to cut outside the tonsil and not through it. The finger is then introduced into the wound and using it as a blunt dissector the tonsillar mass is turned out, leaving it attached to the posterior pillar and by mucous membrane only, which is divided by the ordinary blunt pointed tonsil bistoury. All the tonsillar tissue may thus be removed and there need be no fear of a recurrence of the trouble.

Rational Treatment of Corneal Ulcers.—In all cases of corneal ulceration there is an infiltration of a circumscribed area and more or less suppuration with a consequent loss of tissue. This process irritates the nerve filaments in the cornea and causes the blood vessels to dilate, which brings more blood to the iris and conjunctiva. This causes the escape of albumin into the anterior chamber, makes the excretion of aqueous more difficult, and raises tension. W. L. Phillips (N. Y. Med. Jour., Oct. 3, 1903) has obtained the best results in the treatment of these conditions by using means to contract the arteries and thus diminish the vascularity of the parts. First, he uses suprarenal extract dropped into the eye at least three times a day and as the disease increases, the lung must be instilled more frequently up to ten times daily, depending upon the absorption of the remedy and its action upon the heart. Secondly, because there is almost always a germ present a mild and soothing antiseptic such as boric acid should be frequently employed during the day. To assist in building up the lymph corpuscles and bringing about resolution, he has found that a 5-per-cent. solution of nuclein gives great assistance, and it should be combined with and used in the same way as the suprarenal solution. Furthermore, the conditions which have a bearing upon the local disease must be looked for and treated, for frequently it is found that there is an important predisposing cause in the form of caries, adenoids, hypertrophied tonsils, turbinates, etc. The above method seems to give much better results than has previously been obtained by the use of atropine, cocaine, hot fermentations, yellow oxide ointment, etc., which either tend to increase the vascularity, increase tension or prove too irritating to the conjunctiva.

Treatment of Ozena.—That the *Bacillus mucosus* is the cause of ozena is the belief of A. Casassa (Rev. internat. de Therap. Phys., Oct. 1, 1903), who has studied the effect of a number of bactericidal agents upon this germ in the hopes of discovering a cure. White or colored sunlight or light from artificial sources had very little effect upon the growth of the germ, but radiotherapy proved singularly effective. The virulence of the exposed cultures was very much diminished and white muci survived otherwise fatal injections a much longer time. Clinically, the germs are killed upon the nasal mucosa, glandular activity is stimulated and a permanent cure is established.

MEDICINE.

Localization of Pneumococci.—Bacteriological examination proves that the pneumococci are normally present on many mucous membranes and may give rise to disease in almost every organ of the body. They abound in the mouth, since the alkaline secretion here offers especially favorable conditions for growth. Normally, the epithelial cells offer sufficient protection, so that they must be regarded as harmless. It is surprising that so few cases of tonsillitis depend upon a pneumococcus infection. I. O. Wandel (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 1 and 2) could only find one or two instances among several hundred. The course of the angina is characteristic in that onset and defervescence are sudden and nephritis and joint affections frequently follow. Locally an acute catarrhal, erythematous or pseudomembranous inflammation exists or the tonsil may suppurate. From the mouth the germs may invade the salivary glands, so that a parotitis complicating pneumonia need not necessarily be metastatic. In the nose and nasopharynx the germ is usually as abundant and harmless as in the mouth, but an acute catarrhal rhinitis with slight fever and of short duration may be set up. That general sepsis may, however, follow is evident from a quoted case: A patient died in acute collapse two days after a hemorrhage from a septal perforation was checked, and at autopsy virulent pneumococci abounded in the spleen. The accessory sinuses and meninges may also be invaded, particularly if congenital or traumatic defects exist in the roof of the nose, though the natural channels may also serve as passage-way. The pneumococcus also plays an important rôle in the etiology of otitis media; thus the author found it in 14 out of 15 cases, and frequently in the pus of mastoiditis, periphlebitis, and otitic brain-abscess. In the otitis of measles,

diphtheria and scarlet fever the pneumococcus is usually accompanied by streptococci. The site of preference is pulmonary tissue, but increased virulence is not sufficient here to set up an inflammation; there must also be a diminution of resistance, such as induced by trauma or cold. It is less commonly known that catarrhal pneumonia, peribronchitis and even catarrhal bronchitis are usually caused by the pneumococcus. From the lungs the infection may travel toward the pleura or downward into the peritoneum. Migration through the diaphragm is possible only with diseased pleural endothelia. General peritonitis is rare, for the peritoneum will often show no change or else there is a marked tendency toward encapsulation, and it is probable that many obscure cases of perihepatitis and perisplenitis were originally secondary to a pneumonia. Pneumococci are frequently found in the blood in uncomplicated cases, but an inundation occurs only rarely, and such patients usually die of their sepsis. The portal of entry is not difficult to find since there is a free communication between the alveoli and the capillary system, especially in the stage of red hepatization. In most fatal cases the cocci may be found in the bone-marrow of the vertebræ. It follows that metastases are usually encountered only in the severe cases. Their usual localizations are the endocardium, meninges and joints, especially the ankle, hip and hand. Since the pneumococcus does not find a favorable medium for development in the blood, it need not surprise that infarcts secondary to endocarditis are frequently non-infectious, except in the lungs, where the tissue is already so damaged that suppuration is common. The endocarditis is often characteristic in that the vegetations are very large and brittle, so that portions are easily broken off by the blood. Protracted cases, lasting four to eight weeks, are more apt to suffer from this complication than the typical ones. It is rare to find germs here in the lungs, since they have all migrated into the bronchial glands from where they reach the blood directly or through the thoracic duct. This will also explain why the right side of the heart is more frequently involved. The natural filtering apparatus of the lung will become insufficient as the cocci proliferate and obstruct the lymph-channels so that resolution is delayed and the pneumonia runs a protracted course. In 50 per cent. of the cases the valves are predisposed to inflammation, in the other half the resistance is probably reduced by the general intoxication or by the trauma, which the valves are subjected to by the forcible impact of the thrombotic masses.

THERAPEUTICS.

The Therapy of Radium.—In concluding his review on the physiological and therapeutic value of radium, N. A. NEVZOROFF (Prakt. Vrach, Sept. 20, 1903) calls especial attention to Dr. S. V. Goldberg's report on the use of this substance in the treatment of rodent ulcer. In one case where the ulcer occupied an area extending from the left wing of the nose up to the inner canthus of the eye, and was still rapidly progressing, there was observed a very marked improvement even as early as the sixth day after the first application of a quantity of 75 mgm. of the substance enclosed in a box and allowed to act during a period of one hour and a half; the granulations at the point of application became thicker and firmer, took on a pale, yellow color, and ceased bleeding. Eight days afterward there appeared a necrotic spot, which, however, healed over in a week. The further sittings were at one week's interval, and of one-half hourly duration. Altogether, the patient was exposed to the radium rays for seven hours during a period of two months and a half. It was shown from observations that the effect of the rays resulted in a sclerotic process of the granulations and rapid epidermization of the cicatrix. Thus the effect obtained leaves therapeutically nothing better to be desired. A similar favorable result was seen in another case of rodent ulcer in a woman forty-eight years old. It is difficult to determine which bundle of rays that make up in their complexity the radium rays is responsible for the therapeutic effect. One thing, however, is certain, and that is, that in radium one has a very efficient therapeutic agency, easily applied and not requiring any complicated or costly appurtenances. Moreover, as contrasted with the X-rays the rays of radium are under the perfect control of the operator, and thus their effect can be gradually increased or diminished, and may be employed at a certain distance.

Therapy of Diabetes Mellitus.—In the treatment of diabetes D. LENNE (Therap. Monatshft., Oct., 1903) believes that it is just as important to restrict the proteids as it is to limit the amount of carbohydrates, even in the mildest forms of the disease. He does not believe that diabetic coma is directly caused by β-oxybutyric acid in the blood for many cases have been treated with alkalies for months without averting the fatal catastrophe. The acidification is merely one of the symptoms of a grave disturbance. The assumption that acetone, etc., result from the splitting up of fat is opposed to the observation that large amounts of fat are well tolerated in the gravest cases. Little good was seen from the more recently recommended drugs, such as yeast and melithan, and the writer still prefers the natural mineral waters. Perhaps a pancreatic extract containing only the substance of the islands of Langerhans will yet prove efficient.

Action of Nauheim Baths.—Bathing in the lukewarm, carbonic acid water of Nauheim has very little effect in raising blood-pressure, according to O. REISSNER and G. GROTE (Münch. med. Woch., Oct. 6, 1903). Likewise respiration is but slightly influenced. The area of cardiac dulness percussed smaller, but by also percussing the lungs it was found that this was really due to a dilatation of the lungs. The vital capacity was determined after every bath, and was found slightly diminished. All these phenomena are not due to the carbonic acid or the salt, but to the temperature (34 to 32° C.) of the bath, and exactly the same results were obtained with plain baths of the same temperature or by the application of an ice bag to the precordium. The advantage of the carbonic acid lies in the dilatation of the cutaneous vessels, which it induces, thereby enabling the reaction which normally occurs after every cool bath, to already take place within the bath. The contraction set up by the temperature will therefore be only transient and the patients will soon experience a feeling of warmth. The work of the heart will also be rendered much easier and it is probable that an actual diminution in size occurs, though this can be ascertained only by the X-rays.

The Treatment of Sydenham's Chorea with Large Doses of Arsenic.—Some years ago the well-known French pediatrist Comby recommended the employment in chorea of such large doses of arsenic that they seemed at first rather to be fraught with danger, but subsequent employment proved them to be of great benefit in these cases. M. O. SHAIKEVITCH (Roussky Vratch, Sept. 30, 1903) has subjected this method of treatment, as modified by Tilatoff, of Moscow, to a thorough test. He reports some six cases of Sydenham's chorea, and is forced to the conclusion that there seems to be no foundation either in theory or in fact for the employment of large doses of arsenic as recommended by Comby and Tilatoff. In fact, there are some authors who report a positively deleterious effect from such an employment of arsenic.

SATURDAY, NOVEMBER 28, 1903.

DANGERS OF THE SINGLE "L" MOTORMAN.

A RECENT fatal accident on one of the important elevated systems of the Greater City of New York calls attention once more to the utter inadvisability of trusting large trainloads of passengers, especially during the excitement of the rush hours of the day, to a lone man at the head of the train, with regard to whom there can be no proper continuous and responsible guarantee as to mental and physical health. The ferry-boats plying the waters near the Greater City have now for a number of years been compelled by law to have two men in the pilot house, and it is eminently advisable that this same regulation should be enforced with regard to elevated trains. Practically all the reasons alleged for the necessity for this on boats hold also for trains.

Many things may happen unexpectedly to a man that will make his position of motorman likely to be a source of danger for those whose lives are dependent in all emergencies on his good mental and physical condition. It must not be forgotten that sudden death in our modern life occurs so frequently as to make the possibility of its happening something always to be counted on when the lives of many hundreds of people are dependent on a single individual and that individual so placed that at any given moment he is not under the surveillance of someone assuming a like responsibility with himself. During the ordinary hours of the day usually, at least one of the other trainmen is in position to note any presages there may be of impending danger. During the rush hours, however, the crowd makes this absolutely impossible, and passengers themselves are too uncomfortable, as a rule, to take any precautions looking to their safety.

It is not an unusual thing to hear of engineers being overcome in the cabs of their engines, and the presence of the fireman proving the only means of averting a disaster. It is not necessary that complete unconsciousness should occur, much less that death should take place for a dangerous state of affairs to develop. A workman suffering from the incipient stage of some severe internal ailment, such as pneumonia, or an acute attack of nephritis, may well overestimate his strength in the desire to make a full day, if possible, or he may think that his giving up is likely to be a source of inconvenience to other workmen. Especially if a trip is once begun the motorman is likely to hang on grimly, at least, until the end of it, in order not to block traffic in any way. Under these circumstances his mind is not likely to be in any condition to grasp unusual situations, or realize what must be done in an emergency.

In the last few years there have been not a few cases reported in which railroad engineers on trunk lines, apparently in good health at the beginning of a day's work, have suddenly become irresponsible during the course of a trip, have run their trains by stations where they were scheduled to stop, and have only been saved from bringing passengers into serious danger, to say nothing of travelers at crossings over which the train was run at high speed, by the immediate action of the fireman in the cab with them. Such sudden insane developments are infrequent, and yet they may happen, and even the most carefully repeated medical examinations of the men's condition would not entirely eliminate this source of danger. In cold weather, particularly, it is not impossible that men may, when not feeling well, take intoxicants to such an extent as to paralyze their power for meeting emergencies. This represents another type of mental derangement that cannot be entirely guarded against by ordinary supervision.

There are, therefore, many reasons why the presence of a single man at the head of a long, heavy train, carrying its hundreds of passengers during the rush hours should not be considered sufficient. The recent accident represents the best

possible commentary on it. The blame is put upon the dead motorman. Just how he should have come to make the mistake he did seems utterly inexplicable. It is possible that he was not alive, or was unconscious, at the moment when the collision came. He seems to have made no effort to escape, notwithstanding his realization, if he were conscious at all, of the awful danger in which he was placed. There has even been a hint that the man had occasionally suffered from attacks more or less epileptic in character in which there had been some diminution of right mental feeling and occasionally even losses of consciousness. Such things will happen and even true epilepsy may develop insidiously late in life. With the risk of immediate discharge before them such sufferers are prone to dissimulate and, without a posing passengers to cling to their occupation posing passengers to, cling to their occupation until some mishap betrays them.

It will be said that automatic brakes are installed to meet such emergencies and that if the motorman should take his hand off the controller the cars stop of themselves. The accidents since the transformation of the power to electricity do not confirm this and it seems doubtful if safety contrivances can be invented that will prove sufficent to avert the manifold possibilities of danger. We are about to have an immense extension of electric traction with the opening of the subway in the next few months. It is important that a proper policy in this matter should be initiated before some awful accident leads to an outburst of popular feeling that will compel this measure of safety. It is unfortunately only after some terrible casualty involving the loss of many lives and an immense amount of human suffering that railroad ameliorations looking to greater safety have come. Let us hope that this will not need to be the case in the present instance. During the hours of heavy traffic, at least, all the responsibility should not rest on a single individual or the company and its patrons will inevitably have cause to regret it.

SURGICAL TREATMENT OF EXOPHTHALMIC GOITER.

Although it is generally held that fully fifty per cent. of patients with Graves' disease recover either spontaneously or under the care of the internist, it is a most distressing fact that the disease in the remaining half persistently refuses to yield to any known medication.

The three cardinal symptoms of the disease, the tachycardia, the exophthalmos and the thyroid tumor may or may not all be present. If, however, any one manifests itself to the degree which is common in the obstinate and aggravated forms, it is in itself sufficient to render the patient's life miserable and utterly to prevent him from earning a living. This is often a very sad element in the disorder, inasmuch as the disease is most frequent among young girls.

There is accordingly every reason why continued effort should be made and all research encouraged in the lines of surgical therapy for these otherwise hopeless cases. The criticism may be made that the mortality is high. This is admittedly true even in the hands of men who are pioneers in this work in America.

It is not long since Kocher reported the relief of 60 per cent. of fifty odd cases which he had operated upon for exophthalmic goiter. In all of these he performed a simple hemisection of the gland and in all but six he removed it under a local anesthetic. He reported four deaths in all, and these occurred in the six cases operated upon under major anesthesia. Seventy-six per cent. were cured, 14 per cent. were improved, 3 3/10 per cent. were slightly improved. He acknowledged no failures.

The reports of what is generally known as the Jonnesco operation of sympathectomy, because, although first suggested by Edwards, it was subsequently popularized by Jaboulay and himself, are so far as they go almost as satisfactory. Jonnesco reports 17 cases, in most of which a bilateral removal of the superior and middle cervical sympathetic ganglia with the nerves was done. Of these cases 13 were operated upon by Jonnesco himself and the remaining 4 by French surgeons. The deaths were due to erysipelas and pulmonary congestion. It is said that 10 were cured, 5 were improved and 2 not improved.

Very recently a third mode of treating this disease has been brought to American notice by Dr. Willy Meyer, who records that Lanz, of Amsterdam, has been feeding his exophthalmic patients on the milk of goats who have had their thyroids removed. These goats became cachectic at once and died in about six weeks. The preparation is now relatively easy of access, because it has become a commercial product. Lanz's reports are said to be accurate. If so, he has made a distinct therapeutic gain.

Dr. B. Farquhar Curtis presented a report on his most recent thyroidectomies and sympathectomies at the recent meeting of the American Sur-

gical Association, and judging from the attitude of the members of this most representative collection of American surgeons, his views on the subject are accepted as a standard of work so far accomplished on this side of the water. He says that in the few months since reading the paper his views have not changed materially, and we may therefore consider quotations from his notes as giving us the most recent surgical data. He says that after performing a number of operations for the relief of exophthalmic goiter by hemisection of the thyroid, he became alarmed at the frequency of acute thyroidism (so-called for want of a better name) and attracted by the immediate good results claimed by Jonnesco and Jaboulay for sympathectomy, he began to do the operation seven years ago and has now performed it in seven cases. Unhappily the results have not in his hands been as good as those he obtained from thyroidectomy, for he has had two deaths from acute thyroidism and one possibly due to anesthesia. All the operations were done under ether. Both sides of the neck were operated on at one time except in one case. Dr. Curtis prefers the anterior incision to the incision posterior to the sternomastoid, because it allows access to the superior ganglia without extending so high, and it gives better cosmetic results. In many cases he resected not alone the first and second, but the third ganglion as well. This, of course, is the most difficult part of the operation, because of the depth of the organ.

As to the possible causes and means of prevention of acute thyroid poisoning following surgical operations upon these cases but little is known. There is usually no indication immediately after operation that this grave sequel is to subvene. The temperature will, however, suddenly rise to 102° F. and will reach 104° F. in twenty-four hours, then continue to 106° or 107° F. With the rising temperature the pulse will rapidly run up to 150 or even 200. "The face will be flushed, the breath hurried and superficial, the patient will be nervous, twitching, tremulous, talking a great deal. Anxiety, however, I have not usually known, the mind remaining clear and calm enough to the end. In some cases coma has been present, but this is unusual. In one case, the patient had apparently been sleeping quietly when he awoke with urgent dyspnea and died in a few minutes of sustained arrest of the heart. Morphine will quiet the restlessness, but we can find no means to quiet the heart. Drugs are useless or even make matters worse. One patient only survived these symptoms a period of forty-eight hours."

As yet no sign has been recognized by which this fatal sequel may be foretold previous to operation. Not alone in the well-known gross clinical symptoms, so generally recognized as belonging to this disease has no difference been noted, but in the more refined symptoms as well; in the tremor of the limbs, the increase of resistance to the passage of electric currents through the skin, and in other minor details. Other symptoms give no information on this important topic. Furthermore, both grossly and minutely there has as yet been presented no characteristic differences in the thyroid of exophthalmic patients which might be used as guides. It is of the very greatest importance that some means should be reached whereby clinicians may more definitely choose cases for operative intervention.

As to the causes of acute thyroid poisoning, Curtis believes that it is in no manner due to the presence of the thyroid secretion in the blood, although it has been claimed that it can be avoided by very gentle handling of the gland at the time of operation. It has been shown that if a case of exophthalmic goiter is subjected to any form of operation, this poisoning is apt to occur. It may be due to some form of shock.

These considerations are chiefly of interest to the operating surgeon. For the general practitioner, it is of importance to note that we are apparently upon the borderland of important surgical developments in the treatment of chosen cases of intractable Graves' disease, and that members of the community who are afflicted with the disorder should under certain circumstances be given the benefit of operative intervention.

THE QUESTION OF MEDICAL CHARITIES.

The problem of dispensary abuses is in truth as old as the proverbial hills, and it is about as near to solution to-day as it was twenty-five years ago. This is the verdict arrived at by a committee of the Philadelphia Hospital Association, appointed for the purpose of looking into the methods and results of dispensary practice in that city. The data are exhaustive and as a basis for the conclusions arrived at are indicative not only of existing conditions in Philadelphia but, we believe, are quite similar to those that may be obtained in any American city approaching it in size.

Letters were sent out to 481 physicians and to 61 dispensaries asking for an opinion on the defi-

nitions and functions of a dispensary, its abuses, and the remedies or ameliorations, if any are possible. Besides these, ten practising physicians of high repute were asked for an open statement of their personal feelings in the matter. Every one was heard from, and nearly every one held a different idea as to the extent of the abuse and its possible remedy.

Defining a dispensary according to its use one may say that it is a place where the sick poor may find free medical and surgical relief, and by the sick poor is meant that class of people who can buy food but who, by frequent physical disability, cannot buy anything else. There are just three classes who abuse this privilege and they are the patients who can and will not pay, the patients who would but cannot pay, and those who have neither the "will" nor the "can," and each of these has its representatives in every dispensary in the world, no matter where situated. The Philadelphia Committee is possessed of the idea that under the present dispensary law New York has solved the problem of office practice without pay, but no less a man than Dr. George F. Shrady has recently said that: "It may be broadly stated as the result of exhaustive statistical study, that fully fifty per cent. of the patients who apply for free medical aid are totally undeserving of such charity." And this is perhaps too low a figure, in spite of the clerk and the registrar and the chief and the card system. There are hundreds of seemingly honest people who think that a doctor is or ought to be a sort of philanthropic puppet from whom it is perfectly right to exact as much as can be gotten. They forget that from birth until his twenty-fifth year the average physician has been a constant expense to himself or to his family and that no return begins to manifest itself, even in a small way, until the second year after graduation. These same honest ones would never think of picking anybody's pocket, yet to steal a ride in a railway train or to work on the doctor's sympathies are to them altogether justifiable and are marks of real cleverness.

The closing words of the Committee's report are worthy of quotation: "Direct compensation for services rendered by the dispensary physician would be a long step in the right direction and pave the way for other necessary reforms. Until the patient can be cured of trying to get something for nothing, and until the layman and the physician can both be brought to view the objects of the dispensary from the standpoint of the public welfare, radical reforms must be difficult of accomplishment. Indeed, the education of the community to a proper realization of the object for which the dispensary was founded, combined with unselfish and intelligent service on the part of those responsible for their conduct and management, would seem to be the only real solution of the question.

"The abuses of the dispensary resolve themselves very largely into the defects of human character, which can be observed not alone in these institutions, but wherever large numbers of people are brought together. Higher ideals on every side seem the necessary first step in eradicating abuses. Legal enactment and proper supervision will help toward their realization."

It was proposed by nine of those who replied to the circular letter to decrease the number of dispensaries and keep open only those in direct connection with medical schools. So many of such institutions by charging a low fee cheapen professional labor and make the patient feel that he is after all paying well for what he gets. To do this might prove to be an unwise plan, but even with all our free clinics there are lots of "pay doctors" who treat patients privately and receive nothing year after year, because they desire to aid such and partly for the experience they get out of it. Many a young physician who cannot work in a dispensary would be glad to treat the deserving poor in their homes if he could be sure after some such investigation as the Charities Aid Society are in the habit of making that they are really deserving and not shamming. The adjustment of such a plan would indeed seem to be the proper function of such a society.

Dr. Matthew Woods has spoken clearly and frankly on the question, though we may not entirely agree with him:

"Dispensaries, except in connection with colleges, are an injustice both to the profession and laity. They are crimes and abuses made respectable by being under the protection of law. To relieve both layman and medical man from their burden, stamp them out, as people have no more right to beg under a roof and from people sometimes poorer than themselves, than they have to beg in the open street. When people in this land, except recent emigrants, are so poor that they cannot pay a moderate fee to some struggling physician, their poverty is a crime, deserving punishment rather than encouragement. It is contrary to the spirit of American citizenship to accept anything without rendering a just return."

To the well-established physician it is not a matter of direct interest whether patients are treated free at the dispensaries or not, but to many who are as yet below the half way round of the ladder the question is one of vital importance. Perhaps the incoming administration is looking for just such a chance to show its ability in dealing with civic problems.

ECHOES AND NEWS.

NEW YORK.

Diphtheria Epidemic Up State.—In the village of Suffern, Rockland County, diphtheria is epidemic. Twenty-one cases have already been reported, and the Board of Education has ordered the schools closed. A prominent teacher is one of the victims of the disease.

Physicians' Fees and Small Debtors.—That small debtors can be forced by law to pay up was discovered yesterday when Comptroller Grout was notified by a Fulton street firm, with a claim of $7 against Policeman Walter S. Chapman, of the Canarsie station, Brooklyn, that it proposed to garnishee his salary until the full amount was paid. It was found that at the last session of the legislature a bill was passed, which obtained the approval of the Governor, providing that in all cases where a man or woman makes a salary of $20 per week or over an employer, on legal action being taken by the creditor, shall deduct ten per cent. from the salary of the employe until the judgment has been fully satisfied.

Oldest Woman Physician.—Dr. Amelia Wilkes Lines, the oldest practising woman physician in this country, both in age and period of practice, celebrated her eightieth birthday last week in her quaint, old-fashioned home at 285 Washington street, Brooklyn. She presided all the afternoon at a reception at which were present four generations of her descendants and about 200 old friends, patients, their children and grandchildren. "Why did I study medicine?" she said. "Ah, I am too old to tell you that. It was a great many years ago—half a century. One can forget many little things in half a century." The bright smile in the keen, deep set, blue eyes was understood when the story was learned. It is a sacred subject with the pioneer woman physician. Mrs. Lines was born on the Isle of Wight, Nov. 21, 1823, on the country estate of her father, Sir William Wilkes. She was one of thirteen children, and she centered her affection on her oldest brother, William. When Mrs. Lines was still a child her brother entered the navy as a surgeon. When she was about twelve years old, Mrs. Lines came to America to visit some of her father's relatives in Painesville, Ohio. She took up her residence in America at the death of her father. When Mrs. Lines was sixteen years old her favorite brother died and was buried at sea. When the division of his property was made she asked only for the medical library, instruments and diplomas of her brother. After returning to the United States with these treasures she devoted much of her time to reading the books. The diplomas, from the University of Paris, the University of Heidelberg, the National College and University of London, she framed and hung in her library. With such surroundings she naturally became interested in medicine.

In 1842 she was married to Dr. T. T. Lines, in Painesville, Ohio. Two years later they came to New York. Mrs. Lines had continued her independent study of medicine and worked much with her husband. In 1850 it was suggested that she attend a medical college. The bare suggestion of such a thing astounded the president and faculty of the National College of Amsterdam, which has since passed out of existence. However, as Mrs. Lines was young and pretty and the wife of a well-known physician, she was finally admitted to the classes, after passing an examination in which she led over eleven men out of fifteen. In 1853 she obtained a license to practice in the State of New York, the first granted to a woman in this State. Some time after this Dr. De Laverne, who was a fellow student with Mrs. Lines, was licensed.

Judicial Ruling for Public School Vaccination.—The Appellate Division of the Supreme Court for the Second Department, sitting in Brooklyn, handed down a decision on Friday last, upholding the constitutionality of the statute enforcing the vaccination of school children. The decision was given by the court in the case of Edmund C. Viemeister of the Borough of Queens, who sought to compel the Board of Education and J. H. Meade, Principal of Public School No. 12 in Queens, to admit his child to school, admission having been denied because the child had not been vaccinated. It was urged on behalf of Viemeister that the statute was void, being contrary to the provisions of the Constitution. In the prevailing opinion Justice Woodward declares that the statute does not violate the Constitution, as it operates equally upon every person who is or may desire to become a pupil in the public schools, and affords equal protection to all, and adds: "However willing we might be to agree with the appellant that the practice of vaccination is attended with dangers and that its efficacy is a matter of uncertainty, these are matters which should be properly addressed to the consideration of the legislative department rather than to the courts." Justice Hirschberg also wrote an opinion sustaining the statute, declaring that it constituted a legitimate exercise of the police power.

A Most Worthy Charity.—Under this caption the *Commercial Advertiser* speaks editorially of the work done at the Lying-in Hospital. By calling public attention to charities of this sort the daily press could do a great deal toward the stimulation of benevolence in New York, if it were so disposed. We quote in full: "We called attention a year ago to the wise and beneficent work which the Society of the Lying-in Hospital of this city has undertaken in the new building donated and equipped by J. Pierrepont Morgan, and bespoke for it the generous aid of all persons of means who desired to help forward a most deserving and well-managed charity. The building has been in use for less than two years, and during that period has demonstrated not only its efficiency but its great need in the community. During the past year over 5,000 women applied for admission, and 600 had to be denied for lack of accommodation. An average of 94 a month were treated in the hospital, and a monthly average of 224, or 2,693 in all, were treated at their homes by the society's out-patient department. Of the total number treated over 3,000 were foreign born and only 716 native born. These and many other interesting facts are published in the society's annual report, a synopsis of which appears in our news columns. The fact in the report which we desire to impress upon our readers—that is, those of them

who are blessed with ample means—is that nearly 1,500 applicants were denied treatment through the society's lack of funds. It is not endowed, and depends entirely upon voluntary contributions for its running expenses. At present it has only one of its three ward floors in operation, because of lack of means. This floor has sixty-two beds. If all three floors could be put in operation the capacity of the hospital would be raised to 186 beds, and there would be no difficulty in treating all applicants and thus making the institution what its founder intended it should be, an ample free maternity hospital for the poor of the city. Last year's available income for running expenses was $29,000, while the actual expenses were $117,000. This deficiency of $88,000 was necessary in order to keep the hospital open. It is a distinct public misfortune that so necessary and so beneficent an institution should be cramped for lack of funds. It should not only receive donations amply sufficient to permit of its operation to the fullest capacity, but an endowment fund which would insure it for all time against need in this direction. No one can read the society's report without being convinced that among all the many deserving charities of this city none is more worthy than this, for none supplies for the poor and helpless aid of a more grateful or a more vitally necessary character."

Manhattan Dermatological Society.—Regular monthly meeting held on Nov. 6, 1903, at the residence of Dr. W. S. Gottheil with Dr. L. Weiss presiding.

Dr. B. F. Ochs presented a case which he termed prurigo. The skin involvement began in early infancy and has shown itself in recurrent attacks every now and then. The patient, a girl of nine years, now presents numerous papules of varying sizes on extensor surfaces of forearms and legs, also on chest, abdomen and back. The skin is thickened and all over, except on the face, small subepidermic papules can be felt. Axillary and inguinal glands slightly enlarged. A marked seborrhea of scalp was a peculiar feature. The flexor surfaces of limbs were likewise involved. Dr. E. L. Cocks mentioned the latter peculiarity as unusual in prurigo. Dr. Pisko inclined to call it seborrheic eczema. Dr. Gottheil stated that the marked seborrhea was a feature of the case and always present. (Saw case previously.) The induration, the adenitis and chronicity favored diagnosis of prurigo. Dr. Bleiman called it a mild case; the classical signs of well-marked prurigo were absent. Dr. Sobel stated present condition could be accounted for by its chronic course and the adenitis no more than would be expected in any chronic eczema. He termed it chronic urticaria. An exact diagnosis was impossible.

Dr. W. S. Gottheil presented a boy of nine years with psoriasis of palms and soles. Other (guttate) lesions were seen on elbows, knees, shins, scrotum and penis; the finger-nails were spotted and brittle. Condition has been present off and on for six years. Dr. Bleiman stated that without other lesions on the body to be guided by, these cases often pass for chronic squamous eczemas. Drs. Ochs and Crary spoke of the rarity of the condition as an isolated lesion. Dr. Oberndorfer had seen such cases. This one was typical.

Dr. I. P. Oberndorfer shows the following case: Young man of twenty-one years noticed an oval patch on inner aspect of right upper arm, about the dimensions of a 25-cent piece, also a smaller one near left groin. These patches had raised scaly margins and clearing centres. They were then regarded as tinea tricophyton, but the development of a general pale-red macular eruption two weeks later on the body, with slight malaise, changed the aspect of the case, and Dr. Oberndorfer regards it as a pityriasis rosea; the former large oval patch being looked upon as an initial herald patch. Scrapings, under microscope, showed spores but no mycelia. Diagnosis concurred in.

Dr. A. Bleiman presented a case of lepra tuberosum. The patient, a woman, aged forty-two years, was born in Russia, came to this country nine years ago and claims the disease first showed itself when one year in this country. The tumors were of varying size and numbered several hundred. The face showed the typical leontine expression. The condition has remained in a stationary condition for the last three years.

Dr. Gottheil presented the following cases: (1) Marked seborrhea involving hairy parts of chin, face, upper lip and eyebrows. A severe eczematous condition is present with involvement of the hair follicles; the latter was considered secondary. Dr. Gottheil was inclined to think that owing to the marked seborrheic element, a lupus erythematosus may subsequently develop. (2) Case of lichen corneus (shown at October meeting). As some members then suspected a syphilitic origin, patient was placed on large doses of KI and Hg, with absolutely no effect. (3) Case of atrophia cutis propria, involving lower limbs. (4) A case of feigned eruption. This patient was shown at two meetings previously and diagnosis of pemphigus hystericus made. Again presented this evening with additional bullous lesions. Dr. Gottheil is able to state that the lesions were self-induced by carbolic acid applications. (5) A case of mycosis fungoides (also previously shown) was presented to show the marked improvement following injections of Coley's mixed toxines; treated since midsummer and received bi-weekly injections of 35 to 45 drops. Marked reaction followed the first few doses. Photographs of his former condition were shown and, compared with the subject, it is seen that many of the tumors have disappeared and the subjective symptoms greatly improved. The tumors disappear by absorption. Drs. Pisko and Cocks were skeptical as to the ultimate prognosis. Dr. Cocks adding that he also saw good results in the beginning with the X-ray which later had to be discontinued. Dr. Sobel said to relieve subjective symptoms, much must be accomplished. (6) A case of ulcerative luetic, skin lesions in a female patient, whose initial lesion was contracted about six months ago. The wrists showed peculiar verrucous-like lesions.

Dr. R. Abrahams shows a case of tertiary ulcerative syphilis. About eighteen months ago patient had "some trouble" with her left eye and eyesight temporarily destroyed; also had sore throat and severe headaches. Never noticed any lesions on skin, nor gave history of chancre. Patient seen two weeks ago and shows total destruction of the nasal septum with a beginning ulceration and destruction of the palate.

Dr. B. F. Ochs presented this case for diagnosis: A young woman shows a globular mass just in front of right ear; movable and non-adherent; apparently no connection with the parotid; of four years' duration and only recently tends to increase in size. Diagnoses of fibroma lipoma, chondrosarcoma, etc., were made. A second case by Dr. Ochs, was a girl aged thirteen years, with scratch lesions on face and arms. The history of case strongly suggested self-infliction.

PHILADELPHIA.

The Henry Phipps Institute Lecture.—The second of these lectures will be delivered by Dr. William Osler on Thursday evening, December 3, at half-past 8 o'clock, in the Auditorium of Witherspoon Building, Walnut and Juniper streets, Philadelphia. The subject will be: "The Home in Relation to the Tuberculosis Problem."

The Philadelphia Neurological Society.—At the last meeting of this society, held Tuesday, November 24, Dr. M. Allen Starr, of New York, read a paper entitled "Is Epilepsy a Functional Disease and is it Ever Curable?"

Samaritan Hospital Changes.—Dr. W. Wayne Babcock succeeds Dr. E. W. Holmes, who recently resigned, as Surgeon-in-Chief. Dr. Wilmer Krusen, who has resigned the position of instructor in Gynecology at the Jefferson Medical College to accept the professorship of Gynecology at the Temple Medical College, will be the Gynecologist to the hospital. Dr. F. C. Hammond, who also resigned from Jefferson, will be Dr. Krusen's assistant at the College and Chief of Clinic at the hospital.

Suppression of the Begging Nuisance.—Many cities were represented at a conference to discuss the mendicancy evil and the best methods of dealing with it, held last week under the auspices of the Philadelphia Society of Organizing Charity. An idea of what Philadelphia is doing with the begging classes was given by Police Captain John B. Taylor, who said in part that "From 5,000 to 0,000 vagrants are arrested in Philadelphia every year, and 95 per cent. of them are foreigners." The public itself is largely to blame for the tramp evil through its liberality, but the easy method of conveyance offered by the railroads seems to be the chief method of making tramps. Cheap novels are also to blame, and nearly every boy brought into a police station has at least one on him. In the last five years we have arrested 21,640 tramps. If the public gave 5 cents a day to each of these for that period, the sum would be $300,000, which in the hands of this society would work wonders. One of the results of the conference was the appointment of a committee to co-operate with the railroads in securing some means of driving the tramps from the trains.

Members of Religious Sect Vaccinated.—The headquarters of the Church of God, a negro sect, among whose members five deaths from smallpox have recently occurred because their leaders forbid vaccination, was raided November 20, and 423 persons were vaccinated. Twenty policemen accompanied the vaccine physicians and controlled the excited negroes while they were vaccinated. It has been impossible to make headway in vaccination before, as the people would flee whenever a vaccine physician appeared. Another raid will be made on the church in a short time, as it is believed that a hotbed of smallpox has been located.

Disease Increases as Schools Open.—Important statistics were given at a meeting of the committee of the Public Education Society held recently at the De Lancey school, 1420 Pine street, to arrange for the public meeting in favor of medical inspection of schools, to be held there December 3. Reports of the Bureau of Health for the past four years were presented to show the influence of the schools on the incidence of diphtheria and scarlet fever. The average number of cases per school period were: Diphtheria, 3,895; scarlet fever, 3,684. Average number of cases in vacation periods were: Diphtheria, 2,379; scarlet fever, 2,331. This shows an increase in diphtheria of 39 per cent. and in scarlet fever of 37 per cent.

CHICAGO.

For Model Hospital.—A hotel-hospital, to cost $250,000, will be erected by St. Luke's Hospital in connection with that institution's buildings at 1426 Indiana avenue. The purpose is to supply Chicago with a hospital which will invite the wealthy, not only in this city, but in other cities, to become its patients. Suites will be provided, so that servants can attend the sick persons, and the model will be that of a modern hotel. The end sought, however, is one of extensive charity. By the profits from the patronage of the wealthy the hope is to be able to operate the whole of the existing hospital as a free institution. The project in detail was conceived less than a fortnight ago, but through the efforts of Charles W. Brega, Mrs. J. Ogden Armour, Mrs. John Crerar, Mrs. Marshall Field, Jr., Mrs. Frank O. Lowden, Mrs. Stanley Field, Mrs. Henry C. Dibblee, and other active friends of the institution so much has been done in the interval that the architectural plans already have been drawn. Ground has been bought extending from Indiana avenue through to Michigan avenue, and the new edifice will front the latter thoroughfare. In the new building space will be set aside for free beds, and a wing of the structure will be put to charitable uses if endowments can be secured. The children, rich and poor alike, will have the top floor of the new hospital and likewise its roof, which will be laid out as a roof garden. The workers behind the movement have the promise that when $100,000 has been raised contributions to supply the balance will be made by different wealthy men and women. Of the $100,000 the officials of the hospital have received $75,000, of which $45,000 came as a bequest. Society plans to contribute the lacking $25,000 by giving a charity ball at the Auditorium, which will be a *bal poudre*.

Favor Garbage Incineration.—Incineration rather than reduction of garbage is favored by some of the members of the city council finance committee. After a long discussion it was decided to call upon Commissioner Blocki to suggest an ordinance providing for a separation of refuse as follows: Vegetable and animal matter, combustible material, and ashes. Without separation none of the propositions could be undertaken by the competing companies, according to Alderman Raymer. The question regarding a contract for more than one year was set at rest by the quoting of Judge Tuley's decision adverse to a previous garbage contract for five years. Commissioner Blocki said the city could not pay for reduction and must give the work to a contractor. Street Superintendent Solon said the cost would be $1,000 a day for delivering the separated refuse to stations located by any company. If separation is enforced it is considered that the city may enter into a contract for the reduction or incineration of refuse.

To Assist Hospital Warden.—Dr. John B. Colwell was appointed last week by President Foreman of the county board to be assistant warden of the Cook County hospital. Dr. Colwell passed at the head of the list of applicants at the civil service examination held on October 29 to fill this position. Dr. Colwell is thirty years old, a graduate of Illinois Wesleyan University and Rush Medical College.

New Maternity.—There has just been completed as an adjunct to the Mercy Hospital, what is called the Mercy Maternity. It is a detached building and this institution will be under the direction of Dr. Joseph B. De Lee.

Wesley Hospital Receives a Gift.—Rev. R. D. Sheppard has offered $35,000 to this hospital toward paying off its indebtedness, provided the remainder,

$25,000, is raised within two years. The conditions have been accepted by the trustees of the hospital and they report that $17,000 of the necessary amount is already in sight.

Changes in the Faculty of the Northwestern University Medical School.—A meeting of the board of trustees of this institution was held November 17, when Dr. Chas. L. Mix was elected Professor of Physical Diagnosis, to fill the vacancy left by the resignation of Dr. Geo. W. Webster. Dr. Frederick Menge was elected Assistant Professor of Laryngology and Rhinology, and Dr. William W. Mann was elected Assistant Professor of Ophthalmology and Otology.

CANADA.

Changes in Queen's Medical Staff.—At a meeting of Queen's Medical Staff, held on Nov. 19, the resignation of Dr. Herald as Secretary-treasurer of the Faculty was accepted and Dr. W. T. Connel was appointed to the vacancy. At the same meeting Dr. A. R. B. Williamson was appointed Lecturer on Medical Jurisprudence and Toxicology.

Officers of the College of Physicians and Surgeons of the Northwest Territories.—The following officers of the College of Physicians and Surgeons of the Northwest Territories were elected at a meeting, held at Regina on Sept. 15: President, Dr. M. M. Seymour; Vice-President, Dr. A. B. Stewart; Registrar, Dr. J. D. Lafferty, Calgary; the Executive Committee, Drs. Brett and Kennedy.

New Hospital Opened in New Brunswick.—The Town of Moncton has now a fine new modern hospital, recently built at a cost of $20,000. It was formally opened on Nov. 11, by Premier Tweedie. The hospital is one of the finest institutions of its kind in the Maritime Provinces. The operating room is fitted up with all the latest appliances.

The Toronto Medical Faculty Seeks Better Hospital Facilities.—The Medical Faculty of the University of Toronto and the Boards of Trustees of the principal hospitals are at present negotiating with a view to arranging for accommodation and regulations to secure better hospital facilities for medical education. A need along those lines has been felt for some years and the union of the two medical faculties has paved the way for concerted action by the University and the teaching branch of the medical profession. A committee was appointed consisting of the Vice-Chancellor, Chief Justice Moss, President Loudon, Mr. Irving Cameron, Dr. Primrose, Dean Reeve, Dr. Bingham, Dr. McPhedran and Dr. J. F. W. Ross (Chairman). They drew up a statement embodying the changes and improvements desired and presented it to the Board of the General and St. Michael's hospitals. At the meeting with the Board of the General Hospital, interest in the proceedings was increased by the presence of Mr. Rose Bradford, an eminent physician of University College, London, England, who addressed the Board upon hospital work in London. The proposals dealing first with the subject of house staffs were briefly as follows: That the house staff be large enough to carry on the work efficiently, that one member of each staff be detailed to do clinical laboratory work exclusively, that the staff be divided into seniors and juniors and the seniors retire every six months; that the duties of the house staffs be defined by new rules, that no fee be paid any member of the house staffs by physicians or patients, that each hospital Board should appoint an official anesthetist. Then with a view to increasing the material for clinics, it was urged that all patients in public wards be placed in charge of the clinical staff. The material at present available, the committee stated, for bedside clinics, was deplorably limited. It was proposed that a committee be appointed by each staff to supervise hospital admissions. Closely related to the question of clinical material is the out-patient department. The report stated that a committee of the faculty recently visited New York, Boston, Philadelphia, Chicago, Montreal and Baltimore and reported fully on the value of well-equipped out-patient departments. The out-patient departments connected with the Toronto General and St. Michael's hospitals lack proper organization and must be considered as valueless in their present state. In the General Hospital the rooms are too small, the facilities for handling patients are too meager and the heating in winter is so poor that the health of the patients, the students and the staff is endangered thereby. Better facilities for the study of pathology were asked by the taking of pains to increase the number of autopsies and the keeping of proper records. In the Children's Hospital it is said nearly all the regulations asked for have been in force for considerable time.

Obituary.—Dr. Charles Marshall, Governor of the College of Physicians and Surgeons of the Province of Quebec, which office he has held for two years, died in New York on Nov. 13, of apoplexy. He was a resident of Huntingdon, Quebec, and held degrees from McGill and Edinburgh Universities.

Dr. J. A. E. Steeves of St. John, N. B., died at Phoenix, Arizona, on Saturday Nov. 14, the cause of death being heart trouble. Deceased was forty-two years of age and was considered a leading authority on nervous diseases in the Province of New Brunswick. For many years he acted as assistant to his father, the late Dr. J. T. Steeves, who was Superintendent of the Provincial Lunatic Asylum. He was a graduate of the University of New Brunswick and of Bellevue College, New York.

GENERAL.

Chair of Medical History for University of Maryland.—The University of Maryland has established a chair of the history of medicine, the first of its kind in this country. The occupant is Dr. Eugene F. Cordell of Baltimore. He has written for the *Johns Hopkins Hospital Bulletin* a very interesting essay on the "Doctors and Medicines of Horace."

Typhoid at Williams.—The danger of a typhoid fever epidemic at Williams College is believed to have passed. President Henry Hopkins said last Monday: "I do not anticipate further cases of typhoid among the students. Dr. George Soper, of New York, who had charge at Ithaca during the typhoid epidemic at Cornell, is in charge of the cases here. Everything that could be done to prevent contagion is being done, and it is felt that the situation is well in hand."

Cocaine Habit in Washington.—In his annual report to the District Commissioners Major Sylvester, superintendent of the Washington police force, says that the cocaine habit is greatly on the increase among the lower classes of the capital city and that vigorous measures should be taken at once to check the evil. He says: "It (cocaine) is bound to become a destructive agency unless something is done to prevent its sale by druggists. Two years ago the drug was hardly known, but the habit has grown, and the wreck of lives which accompanies the use of this deadly drug and its sister drugs, morphine, chloral and other pharmaceutical preparations and even patent medicines, is becoming apparent." He also calls attention to the fact that the police are

powerless to raid the opium joints save on the charge of disorderly conduct, and that the fine for this misdemeanor is inadequate to check the evil.

Surgeons' Needles Not Free of Duty.—That "stitching together portions of the human anatomy is not commercially known as hand sewing" is the pronunciamento made by the Board of United States General Appraisers, in overruling a protest against the assessment of surgical needles at 25 per cent. as "needles not specially provided for." A. J. Woodruff & Co. and F. A. Koch & Co., the importers, claimed free entry for them under the clause in the tariff law providing for "needles, hand sewing and darning."

Some Facts about the "N-rays."—In the current number of *Harper's Weekly*, Louis Bell, Ph.D., writes in a very interesting and scientific way concerning the newly-discovered and so-called "N-rays." He says in part: "Therefore the very recent discovery by M. Bloudlot of a new variety of light, which behaves as light ought and yet displays some rather sensational properties, is no small comfort to the puzzled investigator. M. Bloudlot started in to investigate the X-rays, using as an indicator a tiny, faint, electric spark from a little induction coil. The spark flashed more brightly when the X-rays fell upon it, and by its aid he was enabled to measure their velocity and thus to clear up much of the mystery which had surrounded them. Presently he found that with the X-rays appeared a new kind of radiation which obeyed all the ordinary laws of light, although the visible light had already been filtered out of the beam by an opaque screen. The new rays penetrated freely aluminum foil, black paper, wood, and other apparently opaque substances, but were regularly reflected, refracted, and polarized. They were so powerfully refracted by a quartz lens or prism as to appear, at first sight, denizens of the extreme ultra-violet, perhaps only a half-millionth of an inch long. The new radiations are grouped by their discoverer under the tentative name of N-rays. In their properties they are unmistakably light, but of as yet unknown wave-length, and possessing properties which verge upon some of those ordinarily ascribed to radio-activity. Their enormous refrangibility and their powerful action upon electric discharges would naturally suggest a very short wave-length, but their free radiation from comparatively low temperature sources points in exactly the opposite direction. The mere matter of high refrangibility does not decide the question, for substances refract because they slow down the light waves, and disperse the various colors because they slow down and absorb one wave-length more than another. Great local absorption and great dispersion go hand in hand, and they are frequently associated with extraordinary transparency for some particular colors, as if all the opacity of the stuff were concentrated against a single enemy. Thus it appears that while a substance which is fairly transparent to light in general always disperses that light rainbow-wise, with the colors in the order red, orange, yellow, green, blue, indigo, violet, a prism of strongly colored material may mix up the rainbow order in the most shocking fashion. The great refrangibility of the N-rays does not, therefore, prove that they are of short wave-lengths, since quartz has powerful local absorption enough at, unhappily, each end of the spectrum, extreme ultra-violet and extreme infra-red, to account for the most erratic freaks of refraction. Really one sort of refraction is as orderly as the other, in the general consideration of the subject, for, to generalize radiation, there is probably nothing wholly opaque or wholly transparent. We do not know the nature of the complete relation of any one substance to all kinds of light, but the discovery of the N-rays is likely to stretch far the bounds of knowledge."

New Stamford Hospital Gift.—Commodore James D. Smith, president of the Stamford Hospital, announced Nov. 18, at the commencement exercises of the hospital training school for nurses that Robert M. Bruce of Greenwich, who has recently made several donations to that town, had given $10,000 to the Stamford Hospital. This is the first public announcement of the gift. It was learned to-day that it was made over a year ago and that Mr. Bruce requested that no public announcement be made. Mr. Bruce has recently donated $100,000 for a new town hall in Greenwich and has also founded an isolation hospital there.

Quarantine against San Antonio Raised.—Gov. Lanham issued a proclamation Nov. 18, raising the State quarantine against San Antonio, which has been in effect for several weeks because of the appearance of a few cases of yellow fever in that city. Th temperature was down to thirty degrees there Nov. 17, which, it is thought, makes it impossible for new cases to propagate.

Marmorek's Serum in Disfavor.—According to the *Sun*, a majority of the physicians of Paris are skeptical concerning the merits of Dr. Marmorek's tuberculosis serum. Some of the physicians who watched certain experiments say that they were entirely unsuccessful. Reports from Breslau also seems to confirm this unfavorable judgment.

Hospital Reforms in Paris.—The City of Paris is about to spend 45,000,000f. on the work of reconstituting its hospitals. For the past six months a commission has been sitting to investigate the needs of each of the existing hospitals of the capital, and their report shows that but for the enormous strain placed upon their accommodation by tuberculosis patients the number of beds now existing would be sufficient. It has therefore been decided to set apart the sum of 7,500,000f. for the construction of a special hospital for this disease, and to forbid the reception of consumptive patients in the general hospitals for the future. The largest proportion of the proposed outlay will be spent on the Pitié, which, dating from the year 1612, is badly in need of rebuilding. A temporary building will be placed near the huge Salpétrière for the accommodation of the 800 beds of the Pitié during the work of construction, and when finished this hospital will be one of the most remarkable group of such buildings in the world. Every modern invention for the alleviation or cure of disease will be installed with the greatest perfection attainable, and it will even be provided with its own model school of nursing. Two millions will be devoted to the Salpétrière, which is almost a town in itself, and in the front rank of improvements at this and other Paris hospitals is placed the installation of proper laundries. The choice of a site for the hospital for contagious diseases is proving troublesome to the authorities, as the suburbs almost unanimously refuse to have such an institution in their midst.

The Senn Prize Essay for 1904.—The Committee on the Senn Medal begs leave to call attention to the following conditions governing the competition for this medal for 1904: A gold medal of suitable design is to be conferred on the member of the American Medical Association who shall present the best essay on some surgical subject. The award will be made under the following conditions: (*a*) The name

of the author of each competing essay must be enclosed in a sealed envelope bearing a suitable motto or device, the essay itself bearing the same motto or device. The title of the successful essay and the motto or device is to be read at the session at which the award is made, and the corresponding envelope is to be then and there opened and the name of the successful author announced. (*b*) All successful essays become the property of the Association. (*c*) The medal shall be conferred and honorable mention made of the two other essays considered worthy of this distinction, at a general meeting of the Association. (*d*) The competition is to be confined to those who, at the time of entering the competition, as well as at the time of conferring the medal, shall be members of the American Medical Association. (*e*) The competition for the medal will be closed on, and no essays received after, March 1, 1904. Communications may be addressed to any member of the committee, which consists of the following: Dr. James H. Dunn, Chairman, Minneapolis; Dr. M. L. Harris, 100 State street, Chicago; Dr. Floyd McRae, Atlanta, Ga.

Drug Adulteration.—The *Druggist's Circular* of this city in their October issue comment editorially on this subject with such good sense that we desire to give their argument wider publicity. They write: "Forewarned is said to be forearmed. We trust this will prove to be the case with American pharmacists in relation to pernicious and absurd legislation by future legislatures in regard to the placing of responsibility for the adulteration of drugs. The experience of New York with its Bostwick-Dowling Bill should not soon be forgotten. There is every indication already manifest of the determination of the foes of pharmacy to renew the battle in the near future, not only in the State of New York but in other States as well, for the passage of laws that will place impossible tasks and unjust responsibility upon the shoulders of pharmacists. Now is the time to prepare means for the defeat of such efforts and to study the situation in order to have an intelligent comprehension of the charges to be met and the sophistry to be refuted in order to win public sympathy."

"The two weapons depended upon to frighten the public, in order to get them to support such dangerous legislation, are the claims that pharmacists everywhere and in great numbers substitute harmful and cheap for harmless but dear remedies and adulterate, in order to cheapen, the official remedies. To the pharmacist the charge seems too absurd to attempt a refutation but to the public, through knowing nothing definite about the facts, it appears to be reasonable and possibly true. For a long time sensational reports of adulterations of drugs have been published, year by year, by boards of health. The cumulative effects of these reports is beginning to seriously influence the minds of the people so that it is getting to be an easy matter to gain their approval for any restrictive measure that may be proposed. They do not, nor would it be sensible to expect them to, distinguish between adulterations and adulterations. There really should be no need to make such a distinction, but the flexible qualities that have come to be attached to the meanings of that word have rendered it imperative that we know just what a writer means when he uses it, or we will be as badly befogged as he sometimes wishes us to be. By the definition at present attached to it in the reports of some boards of health, the manufacturer has yet to be born who could supply the market with unadulterated goods.

"This may seem to be an exaggerated statement, but it is nothing of the kind. Manufacturers of jellies and fruit juices have been haled before courts of justice and condemned for allowing their products to contain traces of salicylic acid, and now it turns out that the finding of such traces was evidence of the absolute purity of the goods. There is scarcely a fruit that grows which does not, according to the latest discoveries of research science, contain salicylic acid. The laws of several States have made the United States Pharmacopœia the standard of quality for drugs. In such States the chemist of the board of health is bound by this law and his findings could convict every pharmacist in his State for adulterating caffeine citrate. Not a sample can be found in the world that is not adulterated according to this definition of the word adulterate. There has never yet been made a single sample that agrees with the law and probably never will. With three parts of water none of them form 'a clear syrupy solution' which they should do in order to be legally unadulterated. With carbolic acid the Pharmacopœia makes the coagulating of albumin show the absence of creosote, when in fact it would show its presence. In so common an article as lard, the Pharmacopœia declares that it should be insoluble in water, when in fact all lard is slightly soluble in water. Who can find a sample of lard that is unadulterated according to the law? The Pharmacopœia fixes the specific gravity of white wax at 0.965 to 0.975. The actual wax of the world's market is 0.960 to 0.964, according to the reports of experts. All white wax is, if legally considered, adulterated.

"Turning our attention now to the manufacturers we find that they will not or cannot supply the trade with such goods as the Pharmacopœia calls for. When the retail druggist orders alum, even for prescription use, he receives from firms with the very highest character, not the potassium alum of the Pharmacopœia, but ammonium alum that is a wholly different chemical substance. In such a case who is responsible when absolute substitution occurs? Is the Pharmacopœia to blame or are the manufacturers to blame? If milk sugar darkens with the sulphuric acid test because traces of the string upon which it was crystallized adheres, should the manufacturer be accused of adulterating? The preparation is adulterated if we accept the present claims of the law, of boards of health and of sensational reports that now so successfully befog the public. If manufacturers of glycerin, who are no way connected directly with pharmacy, ignore the Pharmacopœia and supply an article that will not withstand our test for fatty acids (as found by La Wall and Pursel), are the pharmacists to blame, is the Pharmacopœia to blame, or are the soap and candle makers to blame? The retailer is, in this case, compelled to sell and use adulterated goods or close his store.

"If the mountain will not go to Mohammed, would it not be well for Mohammed to go to the mountain. The pharmacopœial standard can be lowered. Among many other articles that occur to us now as being exceedingly difficult to obtain in the market, of full pharmacopœial quality, are asafetida, iodine, effervescent citrate of magnesium and nitric acid. In the case of the effervescent salt mentioned, almost all that can be bought is reported to be sulphate and not citrate of magnesium. Who is to blame for the substitution?

"Then there are the analysts themselves. Again and again it has been shown that samples of pharmacopœial drugs when examined by different analysts differed wholly in their qualities in accordance with who happened to be the examiner. His careless work or his ignorance of how to do such work has been a frequent source of trouble. Adulterations of this imaginary kind figure as prominently before the public as deceiving scarecrows as does the work of the most crudite and painstaking who find no such adulterations. In country groceries there are paregorics, essences of ginger, and various tinctures that are fearfully and wonderfully made.

Few of them ever saw a pharmaceutical laboratory and most of them were made by men who know nothing of Pharmacopœias or Dispensatories. Analyses of such concoctions as these swell the flood of damning evidence ued to show the public that restrictions are required to keep pharmacists straight.

"No report on adulterations is worth the paper it is written upon unless it shows that the analytical work was done by a skilful man, that it was checked by a second man who knew nothing of the work of the first, that it distinguished between deliberate sophistication (which is the only real adulteration) and mere impurities incident to manufacture, that the samples were called for from a drug store on prescription and not on five cent orders, that the buyer was a reliable and truthful person, and that every precaution possible was taken to see that there was no mixing of the sample of one house with the sample of another.

"If five cents worth of ether is asked for by the collector the chances are that the druggist presumes he wants it for a toothache application and he gives the 1880 article because he can afford to supply more for the money and thus please his patron. If saffron is asked for, carthamus is almost certain to be supplied instead of crocus. An order by prescription would, at the same store, be certain to get the official articles. To call for potash, soda, sulphur, salts of various metals, and many articles kept for commercial use in one quality and for prescription use in another quality, will bring the commercial grade or the medicinal grade to the purchaser in accordance with the method he pursues in making his purchases.

"Is it fair or just to charge to adulteration goods short of pharmacopœial requirements when such goods were not sold as of standard quality? Yet this is just what sensation loving analysts are frequently doing much to the injury of the good name of pharmacists as a class."

Obituary.—Dr. Allen Hazen of New York, died last Tuesday, after an operation for appendicitis. Dr. Hazen was graduated from the College of Physicians and Surgeons of New York in 1895, and was a member of the Society of Alumni of the City Hospital, where he served as resident physician for two years. He had been on the Board of Medical Examiners of the Mutual Life Insurance Company of New York for about five years.

Dr. Samuel Talmage died at his home, 22 Schermerhorn street, Brooklyn, on Friday. He was born in 1831 at Monte Verde, N. J., and was a son of Major Thomas Talmage of that place. He graduated from the University of New York and began practicing as a physician in Brooklyn thirty-eight years ago. Dr. Talmage was house physician of the Gates Avenue Homeopathic Dispensary and consulting physician of the Brooklyn Nursery. He was a member of the Kings County Medical Society. His wife, a son, and a daughter survive him.

Dr. Herbert A. Starkey, owner of the Sloatsburg Ferry, died suddenly yesterday at Kingston, N. Y., aged thirty-five years. He was a son of Dr. David Starkey of Philadelphia, and formerly surgeon for the Pullman Company, at Pullman, Ill.

Dr. Charles A. Traester, a physician in Williamsburg, died last week in St. Catherine's Hospital of injuries he received on Wednesday, when he fell off a Fourteenth street car. Dr. Traester was born in Hesse-Darmstadt, Germany, sixty-four years ago, and came to America when he was twelve years old. He studied medicine and chemistry and began his business career in the Fourteenth Ward section of Williamsburg.

CORRESPONDENCE.

MEXICO CITY AND YELLOW FEVER.

To the Editor of the Medical News:

Dear Sir: Some time since, I noticed in your general news items, the statement that "yellow fever is prevalent in the City of Mexico." As this is incorrect I knew you would be glad to have it corrected. I believe I am absolutely within the bounds of truth when I say that a case of yellow fever has never originated in the City of Mexico, in the Federal District or on the whole plateau of Mexico, where the altitude ranges from 5,000 to 8,000 feet.

During my residence in this country, over 4½ years, I have known of only two cases in the city; in both cases the disease originated in yellow fever districts, one coming from Vera Cruz and the other from Muna Laredo.

It would be impossible, I believe, for the disease to flourish here, as the conditions are not favorable for its propagation. I shall be glad if you will correct the statement, as it might have an unfavorable effect on the numerous visitors to Mexico. The City of Mexico, since the drainage of the city has been perfected, ranks well in sanitation and general health conditions.

Very truly yours,

A. H. Deekens.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, held October 6, 1903.

The President, Pearce Bailey, M.D., in the Chair.

Partial Paralysis of the Platysma Myoides Following Typhoid.—Dr. Edwin G. Zabriskie presented a girl of seventeen years, a cigarette maker by trade. Following an attack of typhoid fever, five years ago, a sinus formed in connection with the lower jaw on the left side. On coming under observation recently, it was found that there was paralysis of the left platysma myoides, and that this muscle failed to respond to electrical stimulation.

Extirpation of Gasserian Ganglion for Neuralgia.—Dr. William Hirsch presented a woman who had been operated upon one year ago for the relief of trigeminal neuralgia by the removal of the Gasserian ganglion. Microscopical examination showed that the ganglion had been completely extirpated. The neuralgia had been completely relieved. There was no analgesia anywhere. Remak claimed that one result of paralysis of the trigeminal nerve was a pushing of the lower jaw over toward the affected side, associated with partial subluxation. This patient showed only a slight deviation. In this woman the perception of a sweet taste was somewhat uncertain, that for sour was lost, and the taste for bitter was perverted. The electrical reaction of the muscles on the affected side was perfectly normal, but the effect of the current as regards taste had not been noted.

Congenital Multiple Angiomata.—Dr. M. Abrahamson presented a boy of fifteen years, born in Russia after a very prolonged labor. He was cyanotic at birth, and was resuscitated with difficulty. When two months old the mother first noticed a small mass behind the left ear; another appeared on the left side of the neck when two years old after a fall. Since then new ones had appeared. Epistaxis had been frequent, but there had been no hemorrhages from the other mucous membranes. There were a number of these swellings, or angiomata, notably in the tongue and lip. There was an angioma in the retina of the right eye. There were

apparently no angiomata in the liver and spleen. This boy showed both of Virchow's types—cavernous and fissural. The course of the disease in this case was not in accordance with any of the theories that had been advanced to explain such cases.

Dr. William M. Leszynsky presented a boy of eleven years, who had been born at full term by forceps without suspended animation. He had never had convulsions. He seemed perfectly well up to nine months ago, when he began to bend forward when walking. When first seen, on March 9, 1903, his general health was found to be good. The knee-jerks were unobtainable, and the limbs became rigid in various positions. No evidence of organic nervous disease was discovered, and a few days later the knee-jerks were elicited. He was discharged after sixteen days, walking perfectly well, but he was readmitted to hospital in July in a condition similar to the original one. The speaker believed at first that the attitude was imitated, and that subsequently it became a habit. Although the boy walked in a doubled-up position with the head almost touching the floor, he could hang upon a horizontal bar without special difficulty. When in bed, he lay like other children. There were no objective sensory disturbances of hysteria. For want of a better name he would call it a case of hysteria. This habit had persisted, and remained even when he was not observed. There was, of course, exaggeration and a certain element of simulation.

The Movements of Superior Intercostal Muscles in Hemiplegia, and the New Hemiplegic Symptom.—Dr. L. Pierce Clark presented this paper. He said that Gowers expressed the generally accepted opinion regarding the respiratory movements in hemiplegics when he said that in ordinary respiration the two sides of the thorax moved equally, but that in extraordinary respiration there was often less expansion on the paralyzed side. In 1895 Hughlings Jackson stated that in hemiplegics the superior intercostal movements were greater on the paralyzed side during ordinary or automatic respiration, whereas in forced respiration the movement was greater on the sound side. The speaker said that he had examined with regard to this point 161 cases of hemiplegia, with the result that this sign was found to be uniformly present. In destructive lesions of the internal capsule causing hemiplegia the cortical inhibitory control over the medullary respiratory center of the paralyzed side was largely destroyed, and, accordingly, the inhibited medullary center acts excessively in automatic respiration. The experiments of W. G. Spencer demonstrated the presence of an inhibitory center situated just outside of the olfactory tract, anterior to its junction with the temporosphenoidal lobe, and of an acceleration center apparently located in the posterior portion of the sensory-motor area of the cortex. The location of the inhibitory center would lead one to expect it to be damaged in vascular lesions, especially of the middle cerebral, affecting the integrity of the capsular fibers. The fact that the superior intercostals of the paralyzed side were innervated through cerebral fibers ending on spinal centers in the anterior horns of the cord, and the more or less marked damage of the same would account for the general motor loss of volitional acts on the hemiplegic side. The respiratory center could be demonstrated in all muscles bilaterally susceptible of both automatic and volitional movements.

The Advisability of Supplementing the Words Degeneration and Degenerate by Deviation and Deviate.—Dr. G. L. Walton, of Boston, presented a paper with this title. The definitions given by a number of well-known writers were cited to show that a degenerate was one exhibiting certain deviations from the normal type. The words "deviation" and "deviate," therefore, seemed to him to be more accurate, and less objectionable because independent of all theories. Referring to the hereditary aspects of the question, attention was called to the tendency of similar parents to produce inferior degenerates and of dissimilar parents to produce beings superior to their immediate ancestors. The term "degenerate" he would limit, so far as possible, to the lowest grades of constitutional defect, and avoid altogether the anomalous term "superior degenerate."

Dr. Hirsch said that about ten years ago he had himself pointed out the apparent misuse of the term degenerate. The definition which he had given at the time of degeneration was, "a mild development of the psychical organ." The term, superior degenerate, was not originally applied in the way in which it was referred to in the paper, *i.e.*, a degeneration of a lesser degree, but rather that the higher faculties of certain individuals were degenerated. The word "deviation" unfortunately was not one which could be used internationally, and this, in itself, constituted a serious objection to its adoption, although there could be no doubt about the term being superior to degeneration.

Dr. C. L. Dana said that he was very much in sympathy with the purpose of this paper, and that his own views regarding degeneration did not differ very much from those of the author. He understood that Dr. Walton wished to continue the use of the term degeneration in connection with somatic changes. About eight years ago, in an address before the Academy of Medicine, the speaker said, he had defined a degenerate as "one who differed from the average standard of the family from which he sprung," and suggested that there were two classes of degenerates to whom the term could be applied without any implied opprobrium. One of these was the class spoken of in the paper as the "superior degenerate." He thought the term "variation" could be very properly applied. He was of the opinion that in the superior degenerates and in the inferior degenerates, and in the imbeciles, and even in the higher types that there was a degenerative tendency in the germoplasm, and that the family was very apt to die out.

Dr. B. Sachs thought that if degeneration was too severe a term, deviation was too mild a term, for it could not be looked upon as representing anything morbid. After all, the only objection to the term, degeneration, was in its application to the so-called superior degenerate, and the vast majority of the persons to whom the term degenerate had been applied showed a distinctly downward tendency.

Dr. Joseph Collins said that the substitution of terms suggested by the author of the paper did not seem to him a wise move, but an effort to incorporate those terms into medical literature to express certain conditions often included under the terms degeneration and degenerate should be encouraged. Because some of the incident newspapers saw fit to use the term degeneracy merely as a synonym for moral profligacy, and particularly sexual perversion, was no reason for the scientific world to feel called upon to change this term. Even in scientific circles it seemed to him that the term degenerate was used altogether too frequently. He believed that the usual tendency in both superior and inferior degenerates was downward from the normal moral standard, and that this notion was rightly reflected in the definitions quoted.

Dr. Edward D. Fisher said that his understanding of the term degenerate carried with it the idea of a departure from the moral standard, although there were possibly other forms of degeneracy in which the moral aspect did not enter. The term deviation seemed to him entirely inadequate.

Dr. Walton, in closing, emphasized the fact that it was intended, not to displace degeneration, but to furnish a synonym which might prove useful. He saw no harm in the milder word sometimes being used to include the more severe, just as delinquent was meant to include criminal. He agreed with Dr. Sachs that deviate was too mild a word to supplant degenerate, and this was not his intention. If no objection were made to substituting deviate for superior degenerate, the ground would be practically covered. He agreed with Dr. Collins in deploring the elaboration in literature of the individual moral deviations, but this tendency could not be prevented. If we could limit our use of these terms to scientific circles, the word degenerate, as understood in those circles, would satisfy all requirements, but the subject had now become of general interest.

A Case of Cerebral Infantile Diplegia or So-called Muscular Pseudohypertrophy.—Dr. Nathan reported this case. The patient was a large, well-developed boy of ten years. On standing, there was decided lordosis. When lying down, he was apparently unable to raise himself. There was good power in the hands, and the thighs could be flexed without difficulty. He walked with the typical spastic gait. The knee reflexes and the electrical reactions to both currents were exaggerated. The mental development was nil, largely owing to neglect. The case differed from those of pseudohypertrophy in infantile paralysis previously reported in several respects. This was the only case on record, so far as known, in which pseudohypertrophy occurred in a case of so-called spastic spinal paralysis; all previously reported cases were hemiplegic. There were no athetoid movements in this case. The measurements showed that besides the pseudohypertrophy there was enlargement of the left thigh and arm.

Dr. L. P. Clark said that the condition had not been first described by him, as stated in the paper, but by Bernhard, about twenty years ago. Gowers had reported a number of cases about one year later. The case reported here was evidently quite rare. Athetoid movements were noted in only about one-half of the cases, and neither this nor spasticity was sufficient to account for the cases, because this was also frequently absent

Dr. C. L. Dana said that he did not think the diagnosis could be made solely upon the large calves, because this was frequently present in diplegics.

Dr. B. Sachs said that he quite agreed with the last speaker regarding the enlargement of the calves, and suggested that the only positive way of making the diagnosis would be by excising a piece of muscle and demonstrating the characteristic changes.

Dr. J. Collins said that if the contention were that pseudohypertrophic paralysis with spasticity had not been recognized, he would say that during the summer there had been in his clinic a case of typical pseudohypertrophic paralysis in which spasticity was apparently as great as in the case just reported. Although there was profound spasticity, particularly of the adductors, there was no exaggeration of the knee-jerk, and no Babinski—in other words, there were no indications of disease of the pyramidal tracts. The case had been looked upon as a peculiar form of obesity before coming to the clinic.

Dr. Nathan said that it had not occurred to him that there was any doubt about the diagnosis. The history was typical of cerebral paralysis. The child was born asphyxiated, and had convulsions repeatedly up to the seventh year. It began to walk when three years old, and had always walked with difficulty. The only symptom of pseudohypertrophic paralysis was the enlargement of the calves. It was interesting to note that the left side was larger than the right.

NORTH BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held October 8, 1903.

The Chairman, H. Brooker Mills, M.D., in the Chair.

SYMPOSIUM ON SYPHILIS.

Recognition and Treatment of Acquired Syphilis.—This was the title of the paper read by Dr. S. Leon Gans, in which he called attention to the importance of always bearing in mind the essential pathological lesion—the round-cell infiltration. The chancre, he stated, was rather a building up than a breaking down process, and pus is not always present. They usually appear only singly and careful attention should be given to the mixed sore of Rollet, in order to avoid further skin complications. The condition of the epitrochlear and postcervical ganglia should be carefully noted, as should also the history of susceptibility to rheumatism, headache, follicular tonsillitis, cephalalgia, and all mouth and throat conditions; and all the superficial lymph glands should be carefully examined. He dealt at length with the various stages of the chancre and laid stress upon the importance of paying particular attention to extragenital lesions. The chancre is particularly difficult of location in women, being usually of the erosine type. From seven to ten days after the appearance of the initial lesions there is an enlargement of the ganglia accompanied by impaired hyperplasia of the lymph vessels, beginning near the sore and extending over the entire body; the secondary symptoms usually appearing about six weeks after the chancre, although they may be ninety days. He remarked that the early secondary symptoms are symmetrical all over the body, involving the superficial layers; the late secondary symptoms, while often symmetrical, are prone to localization and deeper; and the tertiary lesions are less widely distributed, invading more extensively the particular region attacked, usually unsymmetrical and more prolonged and indolent. The cases which are particularly apt to be overlooked are those in which the syphilides are manifested by only one or two erythematous spots, the subsequent eruptions being delayed for months, or probably never appearing.

Treatment.—Excision was not recommended. The sore should be kept clean, quiet and dry, and iodoform should be employed twice daily, after immersion of the organ in hot water for ten minutes. For the treatment of the secondary lesions, the stomach and skin were thought to be the preferable routes of administration, although in selected cases hypodermics and vapors might be used, believing that the proper course was to wait for the full development of the disease as signified by the early syphilides, in the interim correcting any gastro-intestinal or nervous conditions. Tobacco, whisky and champagne must be eliminated. Mercury is, of course, the important drug, and the method of administration would depend upon the stage of the disease and the individual patient, and in the later stages iodide of potassium is a valuable adjunct. The patient should be warned of his condition and the necessity for strictly following directions, and taking plenty of sleep and careful attention to hygiene. The mercurial treatment should be persisted in for eighteen months to two years, followed by six months' iodide treatment, then interval of six months without specific treatment, and then six months of mixed treatment.

Hereditary Syphilis.—This paper was read by Dr. Howard S. Kinne, in which he stated that the source of infection was either through infected semen from the father or an infected ovum of the mother, and remarked that the manifestations are usually worse in the first child, thus showing that the tendency to transmission is less as the time goes on. It differs from

acquired syphilis in that there is no chancre nor can the symptoms be classed under distinct periods. The chief differential point is the alteration which inherited syphilis impresses upon the nutrition and development, as is evidenced by the fatal marasmus, or acute inflammation of the epiphyses or chronic osteoperiostitis, producing deformity of the bones. The family history should be carefully considered, although the symptoms are varied, and usually appear about six weeks after birth, consisting of coryza, erythematous, or, in some instances, papular rash, soreness of the corners of the mouth, irritation of the laryngeal mucous membrane, and, unless the infection is very light, marked anemia and interference with the digestion and wasting of the body. Antisyphilitic treatment of the pregnant mother will reduce very materially the chances of the offspring being infected. The child should be carefully nourished, preferably breast-fed and proper hygienic measures should be observed. Mercury and iodides should not be given unless symptoms are indicated. He reported the case of a child seven years old, in which the mother was infected about three or four years previous to the birth of the child, during which time she had three miscarriages; was treated for eighteen months, and subsequently there were no marked symptoms. The patient was breast-fed, and with the exception of occasional coryza, was perfectly well until six years of age, when swelling appeared over the metacarpal bone of the right hand, and also over the biceps muscle of the right leg. The swelling on the hand was a fluctuating inflammatory mass, and on incision necrosed bone was found, which was curetted and the patient put on a treatment of $\frac{1}{24}$ gr. bichloride; and 5 grains of potassium iodide t.i.d., the latter being increased 10 grains a week, until he was taking 50 grains t.i.d., which has continued until the present time, the treatment beginning in March, 1903, since which time the symptoms have entirely disappeared and there has been no iodism.

Diagnosis and Treatment of Syphilis of the Central Nervous System.—This paper was read by Dr. Luther C. Peter, in which he considered only those conditions which were due to the direct action of the infection and not the symptoms due to organic changes following long after the disease has disappeared, in which he stated that variability in symptoms, absence of systematic grouping of symptoms, paralysis of cranial nerves, Argyll-Robertson pupils, irregularity of pupillary margin, inequality of pupils, apoplectiform and epileptiform attacks, recurring palsies, usually without loss of consciousness, numbness in extremities, increased reflexes, headache, vertigo and altered mental states are symptoms which point to syphilis of the brain and it coverings. He reported a case of a man, aged forty-three years, who had had a chancre some months previous to coming under observation, and for seven weeks previously had been ailing. A few weeks afterward, he complained of a feeling of "sudden stopping of the heart," as though it had ceased to beat, but did not lose consciousness. He also complained of weight in the right arm and cramping of the fingers when attempting to write. Two months later, when about to get up in the morning, he noticed black specks before his eyes and then lost consciousness; later he suffered from diplopia and paresis of the right side, with increased knee-jerks and marked depression of spirits. The doctor remarked that in syphilis of the cord there is a distinct set of symptoms, characterized by slowly oncoming spastic paraplegia, atrophic at times, contractures of the muscles, involvement of the bladder, slight disturbance of sensation, with a tendency to alternative improvement and relapse, the essential feature being involvement of the entire cord. He reported the case of a man, thirty-nine years of age, first developing several years after the appearance of the chancre, commencing with recurring numbness in the extremities, impairment of the bladder function, diplopia, headache, vertigo, difficulty in speech, at times, spastic palsy of the left leg, partial palsy of the left arm, Argyll-Robertson pupil, impairment of sensation to the touch. He died six years after coming under observation from pneumonia, and post-mortem examination revealed syphilis of the brain and cord and their coverings. The intermittent treatment with potassium iodide and mercury, the latter preferably by inunctions, was recommended, and it was felt that it should be persisted in for several years.

The Recognition and Treatment of Some of the Pharyngeal Lesions of Syphilis.—This was the article of Dr. Lewis S. Somers, Philadelphia, in which he considered (1) the erythema; (2) the mucous patch, and (3) the ulceration. Erythema he believed was frequently mistaken for catarrhal pharyngitis or tonsillitis, especially in private practice. An examination of the erythema, however, will reveal the fact that it presents a deeper brick-red or more of a copper hue, and a marked tendency to the development of small irregular patches of cloudy swelling, which, when they become larger, well-defined and present a whitish or bluish-white color, constitute the mucous patch, the most frequent site of which is on the soft palate, pillars and tonsils, being oval, circular or stratiform in shape. In ulceration, the parts are covered with a thick, mucopurulent, offensive secretion; there is marked tendency to osseous destruction, particularly when the palate is involved. Tuberculosis, lupus, carcinoma and diphtheria may all conflict with this disease, although the former three would usually manifest quite prominent symptoms in other parts of the body, and the latter can easily be recognized by the presence of the specific organism. Three important diagnostic aids are: History of the initial infection; evidences of the disease in other parts of the body, and the response to specific treatment, and, unless one of these is obtained, you cannot be perfectly sure in your diagnosis. He stated that he had obtained the best results in the erythema with protiodide of mercury in $\frac{1}{4}$ to $\frac{1}{3}$ grain doses two to three times daily; the disappearance of the congestion being accelerated in occasional cases by an astringent gargle. The same form of mercury, aided, in some cases, by the application of 20- to 50-per-cent. solution of nitrate of silver, locally, and in others by the local application of a solution of chromic acid, has given the best results. During the late tertiary stage this treatment will sometimes be of no benefit, and may even appear to aggravate the condition, in which case 3- to 5-grain doses of potassium iodide will usually produce marked relief. In the tertiary syphilitic ulceration the destructive process demands checking as quickly as possible, increasing doses of iodide of potash, beginning with 15 to 20 grains t.i.d., in conjunction with protiodide or bichloride of mercury, if necessary, to injection or inunction.

Syphilis of the Eye.—Dr. Wendell Reber read this paper, in which he referred to the impossibility of obtaining a record of just what percentage of syphilitics showed ocular symptoms, owing to the fact that such a history was difficult of elicitation, and in many cases the patient did not realize his condition. He considered the subject under the heads of the primary sore, the secondary or tertiary aspect and hereditary phase. The most usual site for the primary sore is at the margin or just without the margin of the lids, being due to the introduction of some of the poison into the eye. The secondary phase may affect either the cornea, the uveal tract, or the optic nerve and retina, being most fre-

quently in the uveal tract. The work of various authors shows an average of 50 per cent. of all cases of iritis as being specific, which he believed was sufficient ground for suspicioning every case of iritis until trauma, tuberculosis, microbic infection or the rheumatic diathesis has been shown to be causative. Choroiditis is quite as frequently of specific origin as iritis, and is a valuable adjunct to diagnosis. The most frequent tertiary involvements are the intra- and extra-ocular palsies, and these conditions in the absence of diabetes or trauma are usually of specific origin and the forerunners of locomotor ataxia or general paresis. This stage may also be manifested in the optic nerve, lacrimal sac, or iris, the latter being quite rare. Hereditary syphilis is usually manifested by interstitial keratitis, which is characterized by flat nose, bluish gray-white corneas, depressed cheek bones and imperfect teeth, deafness due to inflammation of the auditory canals being a frequent accompaniment.

Dr. F. Savary Pearce felt that the presence of diplopia should always be suggestive of specific disease, especially, when in conjunction with headache, which is usually worse at night, and increased reflexes. The reflexes are usually out of all proportion to the sebasticity, which is due to the fact that the tertiary symptoms encroach upon the nerves and irritate the motor cortex of the brain without destruction. In syphilis of the cord, early involvement of the bladder is an important symptom. In all cases showing suspicious symptoms, where syphilitic history is denied, careful physical examination should be resorted to, and the patient should be impressed with the importance of continuing under treatment for at least three years before he can feel cured.

Dr. Leedom Sharp reported a case of syphilis occurring in a woman, in which he stated that she and her husband were both absolutely ignorant of the fact that he had ever had syphilis. It was manifested first by swelling of the glands, followed later by secondary symptoms. He referred to another case of gumma of the brain, which had been treated by several physicians for stomach trouble, neurasthenia without effect, finally developing periplegia of the left face and left leg, after which she was put on a treatment of bichloride of mercury with good results.

Dr. A. Bernheimer referred to several cases coming under his observation in which there was no history of syphilis in any member of the family, all of which had been very malignant, and suggested the possibility of infection through the tertiary or secondary manifestations of another person. He referred to the case of a girl who had a sore on her lip, which was relieved by zinc ointment, and a few days later there was swelling of the glands and some irritation of the body, which, after the removal of the glands, was relieved by mercury and iodides. He preferred the blue ointment as the method of ministration.

Dr. Carle Lee Felt referred to cases in which three or four children had died from syphilis within a few years, although both parents positively denied the disease, and another child was referred to him suffering from deafness, which was not relieved by iodide inunctions, etc. The case improved on the four chlorides, and the speaker suggested the possibility of this being a case in which the disease had jumped a generation. He also referred to two other cases of deafness from affection of the Eustachian tube, which had been benefited by the use of potassium iodide. Another case in which there was sloughing of the nasopharynx, of a syphilitic appearance, denied syphilis, but after two weeks' treatment with potassium iodide the sloughing disappeared. In conclusion he urged the importance of thorough and long-continued treatment.

Dr. A. Bern Hirsh called attention to the importance of looking after the obscure symptoms of syphilis, and believed that the patient should be thoroughly warned of his condition, and when apparently cured, should be instructed to inform any physician who might in the future treat him for a return of such symptoms, that so many years ago he had had similar symptoms.

Dr. Peter, in closing, felt that as good results could be obtained from small doses of potassium iodide as from the other larger ones. Nervous syphilis, he believed, occurred within six months after the initial lesions, although there are exceptions, one of which had come under his notice in the case of a man suffering from hereditary syphilis, who was entirely free from symptoms from six to forty-five years of age, at which time he had severe meningitis and cerebral ataxia.

Dr. Lewis S. Somers, in closing, called particular attention to the necessity for impressing upon the mind of the patient the exceedingly infectious character of the disease, and referred to a case in which the disease had been contracted by drinking out of the same bucket, or using the same blowing tube at a glass factory. He emphasized the value of tonic treatment in addition to the specific remedies, and laid particular stress upon the importance of large doses in tertiary syphilis of the upper respiratory tract.

Dr. Reber, in closing, believed that diplopia was a very valuable symptom. While he felt that inunctions were important in hospital work he did not favor their employment in private practice.

CHICAGO SURGICAL SOCIETY.

Regular Meeting, held November 2, 1903.

The President, E. W. Andrews, M.D., in the Chair.

Tuberculosis of the Knee.—Dr. Wm. Hessert showed a young man who had been suffering since childhood with a tuberculous knee. Patient had been treated for years by different physicians without avail. He had all the classic symptoms of a typical tuberculous knee. A typical resection was performed. The result was excellent, with shortening of a little more than an inch.

Umbilical Hernia.—Dr. Hessert showed a patient upon whom he had operated for umbilical hernia. The woman had been suffering for nearly thirty years from this hernia. At first the hernia was small, but of late it had assumed enormous proportions and was irreducible. The patient submitted to operation and the author performed a typical Mayo operation. The woman recovered.

Appendicitis with Severe Complications.—The author's third case was one of appendicitis with the usual typical history. After opening the abdomen it was found that the appendix had ruptured, and the stone had escaped into the free peritoneal cavity not far from the appendix. The usual operation was performed. The complications were retrocecal abscess; circumscribed empyema on right side; abscess of right lung which broke into a bronchus, and a second circumscribed empyema on the right side anterior to the first cavity. The patient was treated for these complications.

Dr. A. J. Ochsner said that everyone who operated upon umbilical hernia up to six years ago, before the present method advised by Mayo, knew that there was danger to the patient from edema of the lungs or pneumonia. A large proportion of such cases had a recurrence. With the present Mayo treatment, neither of the conditions named occurred, and the operation was safe and resulted in a permanent cure. He had used the operation in over 30 cases, with excellent results.

Dr. Wm. E. Morgan said that the result in Dr. Hessert's first case had been largely governed by his careful observation and frequent examinations of the patient after primary drainage. The fact that there had been previously an empyema, and an abscess of the lung on the same side, and the further fact that another focus of empyema on the same side was found, showed great diagnostic ability.

Case of Interscapulo-thoracic Amputation for Sarcoma of the Scapula.—Dr. A. E. Halstead exhibited a patient upon whom he performed this operation. Dr. Halstead performed the Paul Berger operation, and mentioned its steps. He said the tumor had been examined microscopically and was found to be a mixed giant- and spindle-cell sarcoma. The patient suffered no shock from the operation, was up on the third day, and left the hospital at the end of ten days. The wound healed by primary intention.

Dr. Arthur Dean Bevan had done three of these operations. The first case in which he performed this operation was carefully gone over by himself and other physicians. The man presented himself with a tumor situated at the upper end of the humerus, and careful examination was made to determine if there was any primary focus anywhere else in the body. No such focus having been found, the conclusion was reached that it was a case of primary sarcoma of the humerus. An amputation was made on the strength of that diagnosis. Histological examination showed that it was a carcinoma. The patient died four or five months after the operation with symptoms of enlargement of the prostate, although he was only forty-five years of age. Examination showed primary carcinoma of the prostate, and that the bone tumor was secondary to it. He narrated the particulars of two other interesting cases, in one of which the tumor was a secondary carcinoma. He said surgeons must be careful not to do what he had done twice, namely, to amputate the entire upper extremity for secondary carcinoma. From his limited experience, many of the cases were secondary carcinomas, having a small primary focus elsewhere. He thought it wise to remove the entire clavicle, to guard against a possible recurrence.

Dr. A. J. Ochsner had done the operation twice, once in 1892, for sarcoma of the shoulder involving the entire joint. The patient remained well after eleven years. The other patient was operated on eight years ago for sarcoma of the shoulder and was also well at this time.

Dr. Halstead, in closing the discussion, said he had had occasion to look up the statistics of the operation at the time he operated on his patient, but did not find them as favorable as many were led to believe. He mentioned the statistics of Schultz, who took all of the cases operated on since 1875, and found an operative mortality of 7.14 per cent.; definitive recovery in 10.71 per cent. He said that his own case presented difficulty in diagnosis. The man had been anesthetized, and an effort made to reduce a supposed dislocation of the shoulder joint. This brought up the question of false aneurism or hematoma, which was excluded. A diagnosis was made by eliciting crepitation, which he said was characteristic of giant-cell sarcoma. Repeated examinations of the urine showed the presence of albumose, a common symptom of this particular form of sarcoma. This did not exclude osteomyelitis, but after introducing a needle into the tumor and nothing but fluid blood being withdrawn, osteomyclitis was excluded and this left nothing but sarcoma to be considered

The Pathology and Treatment of Recent Fractures of the Patella—Dr. S. C. Plummer, of Chicago, Ill., read this paper.

After considering the arguments for and against the operative treatment, he proposed the following as a fair statement of the present status of the question of treatment of recent simple transverse fracture of the patella: (1) Operative treatment should never be undertaken except under the best of conditions for maintaining asepsis. (2) Presupposing ideal aseptic conditions, not every case should be subjected to operation, but only those in healthy patients of suitable age, with at least half an inch of separation of the fragments and lateral tears which compromise the "reserve extension-apparatus," or in patients following arduous occupations. (3) The operative treatment fulfils all the indications for treatment in a manner which the non-operative method can only partially achieve, but good functional results follow the non-operative treatment as a rule. (4) Early massage in all cases favors the early and complete restoration of function of the joint, and should be used in all cases. (5) If operative treatment is employed, the open arthrotomy should be used. (6) Absorbable suture material applied to the soft parts is sufficient in nearly every case.

Dr. Daniel N. Eisendrath was glad to hear the conclusions of the essayist that surgeons should not employ the operative treatment for fracture of the patella unless the surroundings were favorable. As to the treatment by non-operative methods, if the pathology of fractures of the patella was borne in mind, and treatment directed accordingly, almost as good results could be obtained with the non-operative treatment as with the operative. The pathology consisted of extensive tears in the aponeurosis as well as of the bone itself, with a large amount of effusion into the joint. If a posterior splint was applied, even though there was not exact coaptation of the fragments, by having massage applied regularly every day, for the purpose of getting rid of the effusion, and also of preventing atrophy of the quadriceps, which delayed extension, good functional capacity could be effected after three or four months. He did not agree with the essayist in advising the beginning of passive motion at the end of the fourth week, and called attention to a case which he exhibited to the Society last winter, in which he sutured the patella, with accurate approximation, but did not begin passive motion until the end of the sixth week. As suture material he thought kangaroo tendon was ideal.

Dr. D. A. K. Steele thought most surgeons had reached the conclusion that in the simpler transverse fractures of the patella, with a minimum amount of violence, the non-operative treatment should be employed. However, in cases of fracture of the patella due to direct violence, in which the soft parts had been materially injured, or where there had been a stellate fracture of the patella, the open method of treatment gave by far the best results. True bony union could be better obtained by the use of sutures.

Dr. Wm. E. Morgan mentioned two cases which showed how surgeons were obliged sometimes to treat one fracture differently from that of another. He reserved operation as a secondary procedure in all fractures of the patella that were not compound. His results from conservative measures in ordinary fractures without operation had been just as good as from suturing. He would postpone suturing until he was convinced that useful union could not be obtained by the ordinary methods of dressings.

Dr. Thomas A. Davis narrated the case of a patient who had sustained three fractures of the patella from indirect violence. There was extensive interposition of the soft tissues between the fragments. The patient in alighting from a train sustained a transverse fracture of the patella. There was separation of one-third of

an inch; also considerable swelling of the joint. After a few days' rest, massage, and hot applications to the joint, an incision was made and the patella wired with silver wire after drilling holes through the fragments. Several months later the patient sustained a fracture of the other patella under precisely similar circumstances. He found a separation of from 2½ to 3 inches of the fragments which he had first wired, also separation of three-quarters of an inch of the recently fractured patella. He operated on the recently fractured patella first, and later on the other, wiring the fragments. The patient was now perfectly well and attended to his business.

Dr. Charles Adams said that suturing of the fractured patella depended upon the surroundings of the surgeon. If he were in a place where he could depend upon asepsis, he would be inclined to suture most of the cases. The cases he has sutured have done very well. The surgeon was bound to restrict operative intervention to those cases where the soft tissues were interposed between the fragments, or where it was impossible to secure good apposition without the aid of some ligature. For suturing he had found that kangaroo tendon answered the purpose admirably.

Dr. Plummer, in closing the discussion, said there was a wide variance of opinion among writers as to the time for beginning passive motion. Scudder had advised beginning passive motion at the end of the fourth week in non-operative cases, and at the end of the second week in operative cases.

Demonstration of McGraw Elastic Ligature.—Dr. A. J. Ochsner said that this ligature was applicable to gastro-enterostomy in which the pylorus was not completely obstructed either by carcinoma or cicatricial constriction. It was likewise applicable for making anastomosis between the intestines. The operation could be done as quickly by it as by the Murphy button. It took about the same length of time. He had used the McGraw elastic ligature in 40 cases, with three deaths.

Dr. D. A. K. Steele asked whether in any of the 40 cases referred to serious symptoms had occurred from acute intestinal obstruction where the elastic ligature was used.

He said the objection to the elastic ligature and to the Murphy button was that these devices worked while surgeons were asleep. Personally, he liked to see the work finished. In any mechanical device that was used, one had to depend upon the element of time; it took hours or days for the elastic ligature to perform its function, which was somewhat uncertain. The same was true of other mechanical contrivances. He agreed with Dr. Ochsner in saying that ultimately surgeons would have to come to the use of the needle and thread.

Dr. E. Wyllys Andrews said he began to use the McGraw elastic ligature soon after the publication of Dr. McGraw's original paper. He had employed it in a dozen cases, with one death. The elastic ligature, he thought, was a little quicker device than the Murphy button and had all its advantages. It had the additional advantage over the Murphy button, in that the surgeon did not have to open a hollow viscus which might infect the peritoneum.

Dr. Arthur Dean Bevan was interested in hearing Dr. Ochsner report forty cases, with practically no operative deaths. This meant a great deal, and yet, when one turned to the work that had already been accomplished with needle and thread, the results were excellent. For instance, he mentioned the admirable report of Munyon, of 76 gastro-enterostomies, with only one death, by means of needle and thread.

Dr. Ochsner, in closing, said that practically he had never done a gastro-enterostomy that was as satisfactory as it was by the use of the McGraw ligature, but he desired it to be understood that he did not consider it the final thing. He felt that if he could do the operation as well as Munyon had done it with needle and thread, he would not use the McGraw elastic ligature. As to the remarks of Dr. Steele, he said the case referred to was one in which Dr. Mayo had made a Mikulicz gastro-enterostomy with the elastic ligature, and later intestinal obstruction occurred from inclusion of more than ½ of the circumference of the intestine in the grasp of the elastic ligature.

BOOK REVIEWS.

A Text-book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D., Professor of the Practice of Medicine and of Clinical Medicine, Medico-Chirurgical College, Philadelphia. Sixth edition, Thoroughly Revised. W. B. Saunders & Co., New York, Philadelphia and London.

The fact that 21,000 copies of Dr. Anders' Practice of Medicine have been sold in about four years is conclusive proof that the work is popular among the medical students and physicians of this country. There are many features that commend it. The arrangement is such as brings related subjects closely and logically together, and in such a way that the consultation of various parts is ready and easy. The portions devoted to treatment are especially full and practical, and methods of diagnosis are given with a clarity and attention to detail that make their application, even in the hands of the physician unaccustomed to some of the technical details described, facile of accomplishment.

Among the new subjects treated in the present edition are paratyphoid fever, the fourth disease in the measles-scarlet fever group, trypanosomiasis, orthostatic albuminuria, a better name than the cyclic albuminuria of the older text-books, transcortical aphasia, adiposis dolorosa (Dercum's disease), and amaurotic family idiocy. As the names of these will indicate, no attention is spared in successive editions, and no delay allowed to occur in the exposition of new subjects. The work is evidently from the hand of a practical teacher, who realizes what the difficulties of the medical student are (and what physician does not remain a medical student in our day?), and who is able to present very clearly just the material necessary to solve such difficulties.

A Text-book Upon the Pathogenic Bacteria. By Joseph McFarland, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Philadelphia Hospital and to the Medico-Chirurgical Hospital, Philadelphia. W. B. Saunders & Co., New York, Philadelphia and London.

Dr. McFarland's Text-book upon the Pathogenic Bacteria is in its fourth edition, an index at once of the popularity of the work and of the general interest among physicians in this comparatively new subject. The present edition contains some noteworthy features and especially a full set of bibliographical references to original papers of value in bacteriology, and to the literature of recent advances in this progressive subject. Notwithstanding considerable additions, by the judicious use of smaller type, the number of pages has not been increased.

We have read with special pleasure the chapters on the biology of bacteria and on immunity. Nothing is clearer than that for the proper understanding of bacteriology and its applications to sanitary science, especially as regards the preservation from contamination of

food materials and drinking water, physicians will have to understand the principles of the biology, or life-habits of the bacteria. The chapter on immunity contains the best and clearest brief exposition of Ehrlich's theory and its relations to Metchnikoff's teachings with regard to immunity that we have as yet seen. This subject is of very living interest at the present moment, and owing to the long terms employed and the absolute novelty of some of the ideas exploited, has been a source of no little confusion to ordinary practitioners. Dr. McFarland's book in its constant progress, with repeated revision, seems destined to become one of the classical text-books on the subject of bacteriology.

A Text-book of Pathology. By Alfred Stengel, M.D., Professor of Clinical Medicine in the University of Pennsylvania. W. B. Saunders & Co., New York, Philadelphia and London.

Dr. Stengel's Text-book of Pathology, in its fourth edition, has been not only revised but considerably enlarged. The best proof of how great are the advances in modern pathology is to be found in a comparison of previous editions of this book with the present, in which, necessarily, a considerable portion of the work has had to be rewritten. There is a new chapter on the technic of pathological methods that will add greatly to the value of the book for medical students. The subject of immunity occupies a very important chapter, and is treated very fully and clearly, as becomes its present importance in medical literature.

The whole book bears evidence of being the work of a teacher of medicine, closely in relation with students and their actual difficulties. It has not been written from the distant standpoint of the lecturer, giving his information in his own way and without that careful attention to students' ways of understanding, which are often quite different from the viewpoint of the interested specialist. It is this practical teaching note in the book that has given it its popularity in the past, and will continue to prove its best-selling quality in the future.

Clean Milk. By S. D. Belcher, M.D., Research Worker in the Rockefeller Institute for Medical Research, Attached to the Research Laboratory of the Department of Health of the City of New York. With an Introduction by W. H. Park, M.D., Professor of Bacteriology and Hygiene in the University and Bellevue Hospital Medical College and Director of the Research Laboratory of the Department of Health. The Hardy Publishing Co., New York.

In his introduction, Dr. Park shows that the insistence on a proper nutritive value and the prohibition of the use of preservatives are not sufficient to insure a good milk supply, but that of more importance still is the freedom from bacterial contamination. Long before milk has become sour to the taste, it may contain enormous numbers of bacteria and has usually become unwholesome. The number of bacteria is, therefore, the best means of determining whether the milk is clean and fresh. As a part of the movement for the improvement of the New York City milk supply, the author, by means of a grant from the Rockefeller Institute for Medical Research, and under the supervision of Dr. Park, visited a number of the dairies and farms which contribute to the city's supply of milk. Taking into account then the methods daily put in practice by the best of our dairies, as subject to bacteriological testing, the writer endeavors to set forth practical measures for use on a large or small scale for the exclusion of bacteria from milk. Veterinary and agricultural questions are not considered, but every means by which the number of bacteria may be limited. This includes the situation and care of pasture, cow-yards, and barns, the cows, the milkers, the cans, the bottling, and the getting of the milk to the consumer. Numerous photographic pictures add to the value of the text, which constitutes an evening's pleasant and instructive reading.

Functional Diagnosis of Kidney Disease. with Special Reference to Renal Surgery, Clinical Experimental Investigations. By Dr. Leopold Casper (Privatdocent an der Universität), and Dr. Paul Friedrich Richter (Assistent der III. med. Klinik), in Berlin. Translated by Dr. Robert C. Bryan, Adjunct Professor Genito-Urinary Diseases, University Med. College, Richmond, Va., and Dr. Henry L. Sanford, Resident Surgeon Lakeside Hospital, Cleveland. P. Blakiston's Son & Co., Philadelphia.

This little book contains an excellent résumé of recent work on the kidneys, especially as regards newer methods of determining their sufficiency. Cryoscopy receives full and clear treatment, especially as regards its usefulness for surgery. Dr. Casper's name especially is a guarantee of the thoroughly scientific quality of the book and also of its practical character. Excellent hints for ureter cystoscopy are given and the book will doubtless prove extremely interesting and useful for those engaged in such work.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Psychotherapy. By Dr. Sheldon Leavitt. 8vo, 247 pages. Garner-Taylor Press. Chicago.

The Principles and Practice of Hydrotherapy. By Dr. Simon Baruch. Second edition. 8vo, 487 pages. Illustrated. Wm. Wood & Co., New York.

A Text-Book of Clinical Anatomy. By Dr. D. A. Eisendrath. 8vo, 515 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

A Text-Book of Pathology. By Dr. Alfred Stengel. Fourth edition. 8vo, 933 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

A Text-Book of the Practice of Medicine. By Dr. Jas. M. Anders. Sixth edition. 8vo, 1,300 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

The American Illustrated Medical Dictionary. By W. A. Newman Dorland. Third edition. 800 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

Nervous and Mental Diseases. By Drs. Archibald Church and Frederick Peterson. Fourth edition. 8vo, 922 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

A Text-Book Upon the Pathogenic Bacteria. By Dr. Joseph McFarland. Fourth edition. 8vo, 629 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

Clinical Examination of the Urine and Urinary Diagnosis. By Dr. J. Bergen Ogden. Second revised edition. 8vo, 418 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

THE INFLUENCE OF PASTEUR ON MEDICAL SCIENCE.*

BY C. A. HERTER, M.D.,
OF NEW YORK.

TO ONE who treasures memories of student days spent in your pathological laboratory, when each member of a small and favored group worked under the personal guidance of the great teacher whose unselfish labors have done so much for science in this country, it is indeed an exceptional privilege to address those who represent the School of Medicine that has grown since then to be the model for many an older institution. Yet I am conscious that this very privilege entails a risk proportioned to the largeness of the opportunity of using unworthily the precious moments which fortune has bestowed on me. My choice of subject has not, I fear, lessened this hazard, for I have chosen to speak to you of one of the most significant men of the past century, whether we consider him as a person, as an investigator or as a public benefactor. I pray you, therefore, deal gently with the shortcomings of an undertaking so difficult and ambitious as that of estimating the influence of a great career on the advance of medical science.

Louis Pasteur first saw the light of day on December 27, 1822, in an humble dwelling in the little town of Dôle in the Franche Comté. His parents had small means and limited social opportunities, but through the exercise of forceful character and unusual fidelity to elevated ideals of life, managed to give him a fair elementary education. The father, earnest, industrious and intellectually ambitous, instilled into his son the desire to become a useful and respected member of society, shielded him by constant companionship from the vulgar temptations of youth and fired him with a love of country which a long and honorable career as a soldier of Napoleon had strongly fortified. The mother of young Pasteur was prevented by household cares from sharing closely the intellectual interests of her only son, but showed the depth of her affection by making many a little sacrifice to further his education. She was a spirited woman, possessed of lively imagination and quick intelligence, and it is reasonably clear that the unusual artistic preceptions of Pasteur mark the perpetuation of these maternal gifts. Although the school days of Pasteur appear to have given little indication of an exceptional future, the lad showed some qualities which distinguished his work in later life. In his daily tasks, at which he worked faithfully and deliberately, he showed the most scrupulous accuracy and truthfulness, attributes which are the more noteworthy for the reason that they belong to a temperament enriched with a strong vein of romanticism, which for a time found expression in a fervid devotion to poetic literature. Moreover, Pasteur showed while still in his teens a pronounced capacity for portraiture. During his three years of instruction at the Collège Royal of Besançon, which he entered at eighteen years of age, the young student was more absorbed in literature and art than in science, and impressed his colleagues as being surely destined for an artistic career. The courtesy of Mr. Philip B. Marcou, of Cambridge, has made it possible for me to examine closely two fine examples of Pasteur's work at the end of this Besançon period. Although these portraits disclose the manual hesitancy of the imperfectly trained craftsman, they bear an unmistakable air of distinction and are executed with a respect for detail which is highly remarkable. Anyone who sees these youthful works is likely to feel that eyes so sensitive to these minutest particulars of form, would be apt to see many things which others had failed to notice; and it is noteworthy that Emil Fischer, whose calm judgment is well known, has expressed his belief that Pasteur's crystallographic discoveries were facilitated by his artistic perceptions.

The years at Besançon were followed by a highly important course of study at the Ecole Normal of Paris, during which Pasteur formed the determination to devote himself to science. For the first time in his life, the gifted impressionable young man found himself under the influence of a creative scientific mind of the highest order, a mind which has left a large and permanent mark upon the history of chemistry and which could not fail powerfully to mold the plastic intelligence of Louis Pasteur. Jean Baptiste Dumas, who had already discovered the great principle of substitution, united to his genius as an investigator the charm of a finished and spirited delivery. His Sorbonne lectures fairly captivated the young student and gave definite and lasting direction to his study and fancy and, later, to his researches. Other teachers of a superior order contributed to lead Pasteur into the promising and fascinating paths of physics and chemistry. The attractive Balard, to whom bromine had first surrendered the secret of its existence, reinforced the chemical teachings of Dumas, and the admirable lectures of Delafosse aroused an enduring interest in the subtle beauty of crystalline forms. But it is to the strong intellect of Dumas that Pasteur owed his first grasp of the great principles of science and that enthusiasm for work, which made it possible to ignore the harsh and depressing material conditions that prevailed at the Ecole Normal.

*Address delivered at the opening of the Johns Hopkins Medical School, 1903.

The recognition by young Pasteur of the importance of correlation in the physical sciences is an impressive feature of his mind at this period of close association with great chemical investigators. Evidence of this recognition exists in a singularly fine letter, full of enthusiasm for science, which he wrote to his colleague, Jules Marcou, then entering on his distinguished career as a geologist.* "Before finishing your letter," says young Pasteur, "I had already regretted that your studies in chemistry were incapable of responding to what geology will often ask of them." . . . "I know very well that many distinguished geologists have no broad conception of chemistry, but I believe this to be a great pity and I think that geology has not often enough turned to chemistry." The chemist of twenty-three summers held a point of view which was destined very soon to aid him in a memorable research.

It was in the field of crystallography that Pasteur, led by an interest in the ingenious and delicate methods of the science, first showed his exceptional capacity to observe minutely things and processes and to correlate and interpret the results of his observations. He began by carefully repeating a series of crystal measurements on tartaric acid, racemic acid and their salts, shortly before published by Provostaye. During the study of the recrystallized salts of tartaric acid he observed one very important but unobtrusive thing which the distinguished physicist had overlooked—regular evidences of hemihedral facets. All the tartrates showed a weak kind of isomorphism which is apparently forced on them by the tartaric acid group, whatever other element may exist in the compound. Guided, as he tells us, first, by the observation of Biot that tartaric acid and its compound rotate the plane of polarization, secondly by a relationship between the crystalline form of quartz and the direction of rotation, and finally by Delafosse's conception that hemihedrism depends on definite crystallographic laws, Pasteur concluded that there is a relation between the hemihedrism of the tartrates and their optical activity. An unexpected discovery soon proved this to be true in a conclusive and beautiful manner. One day in the dark library of the Ecole Normal Pasteur's eyes lighted on a remarkable paragraph from the writings of the Berlin chemist and crystallographer, Mitscherlich, relative to two different saline combinations of tartaric acid, the tartrate and the paratartrate (or racemate) of sodium and ammonium. This note stated that these two types of double salts have the same chemical composition, the same crystal form with equal angles, the same specific gravity, the same double refraction, and that in consequence of this their optical axes form the same angles. Their water solutions have the same refraction. The dissolved tartaric acid salt rotates the plane of polarization and the racemic salt is indifferent, as had been found by Biot for the whole series of salts. "But," continues Mitscherlich, "the nature and the number of atoms, their arrangement and their distance from one another are the same in both bodies." The contradiction expressed here upset all Pasteur's physicochemical ideas and persisted for months in his mind like an interrogation point. But the day came when experience cleared up the mystery by demonstrating that there is really a difference between the tartrates and the racemates which Mitscherlich had not noticed. The former bore hemihedral facets on the right side and always rotated the plane of polarization to the right; the latter bore facets both on the right and on the left sides and did not rotate polarized light at all. Moreover it later appeared that this inactive racemic acid may be caused to crystallize in such a way that the crystal mass consists of equally numerous dextrorotary and levorotary crystals, the former possessing hemihedral facets on the right side, the latter hemihedral facets on the left side. Both kinds of crystals were isomorphous, but the isomorphism was that of two asymmetric crystals, of an object to its reflected image. The weighty and surprising discovery had been made that indifferent racemic acid crystallizes into equal quantities of ordinary dextrorotary tartaric acid and the newly observed levorotary tartaric acid.

This research on the tartrates, culminating in 1848 with the discovery of the nature of paratartaric or racemic acid, proved that Pasteur had already made himself master of the experimental method.

Three distinct practical results followed in the train of this research as a consequence of continued studies of the crystallographic problem. In the first place there came to light numerous fresh evidences of a relation between molecular constitution, crystalline form and the property of rotating the plane of polarization. It is true that Pasteur seriously entertained some ideas of a highly speculative nature regarding the operation of dissymmetry in nature, ideas which involved him in fruitless experiments; but on the other hand the tangible and positive results of his work must be recognized as forming the basis of the modern doctrine of the asymmetrical carbon atom which has so illuminated our ideas of the spatial arrangements of the atoms within the molecules of organic substance. Secondly, the research on the tartrates led Pasteur to the recognition of a series of optically inactive compounds, including inactive malic acid and inactive amylalcohol. Finally, the crystallographic researches were the bridge over which the far-seeing investigator passed on the way to lay the foundations of a new biological science, a science which has effected a veritable revolution in our conceptions of medical problems. Cagniard-Latour, Schwann and Kützing, by knowledge gained in their experiments on alcoholic fermentation held one pass to the great secret, but saw not the fields of discovery to which it might have led them. Pasteur made his way thither by a singularly trustworthy intu-

* Mr. Philip B. Marcou has permitted me to read a large number of unpublished letters written by Pasteur to his father. The letter above quoted is dated June 10, 1845, and is one of a very small number belonging to this period.

ition. Greatly impressed with the circumstance that optically active substances like the sugars, the tartrates, the malates, the citrates, the gums and the proteids seemed to be confined to the organic world and were not to be found outside the tissues of plants and animals, Pasteur made a simple yet decisive experiment. To some pure crystallized inactive ammonium paratartrate he added fermenting albuminous material. After a time the fluid was examined with the polariscope. It rotated strongly to the left. This levorotation was obviously due to the fact that the dextrorotary constituent of the paratartrate had been decomposed. An optically inactive fluid had been converted into an optically active fluid. According to Pasteur's theoretical views this striking change indicated the mediation of living matter. The activity of unorganized purely chemical ferments could not, in his judgment, explain the facts; microorganic life must be in some way concerned Fortunately the mind in which this conception was born was also capable of testing its correctness by the most rigid methods of investigation. Fortunately, too, the external conditions favored a studious excursion into the processes of fermentation, for Pasteur was called in 1854 to a Professorship at Lille in a region of distilleries which involved the training of young men to proficiency in industrial chemistry and made it essential to get new light upon the various kinds of fermentation.

At this period of Pasteur's career the prevalent doctrines of fermentation were singularly unsatisfactory and uncontrolled by searching experimentation. The versatile Spallanzani had nearly a century before taken the important step of showing that putrescible liquids can be permanently protected from the processes of fermentation and decomposition by boiling and exclusion of air. Then Gay-Lussac, inspired by the revolutionary but constructive work of Lavoisier made his clever attempt to show that the results of Spallanzani were due to the exclusion of the oxygen of the air from the decomposible materials, and the ingenious French cook Appert put this erroneous idea to important practical use in his widely employed method of canning perishable foods.

Thus in the early days of the nineteenth century people were content to think of alcoholic fermentation as purely a chemical process. The first great blow to this widely accepted doctrine came from Theodore Schwann's incisive studies of the yeast plant in its relation to alcoholic fermentation. Very clearly did Schwann show that oxygen does not suffice to initiate the fermentation of sugar and that the necessary condition is the presence of something which is destroyed by heat—a living organism. Unfortunately he failed to maintain aggressively the new doctrine of the dependence of fermentation on micro-organic life. The result was that the new vitalistic hypothesis failed to make any important advance in the face of the sharp criticism and ridicule of so active and influential a teacher as Justus Liebig, whose word was nearly everywhere received as final in matters chemical and physiological.

To Liebig and to many others it seemed a retrograde step to assume that a living organism like the yeast plant is the cause of alcoholic fermentation, for the most advanced scientific thinkers were eagerly striving to explain the phenomena of life by physical and chemical laws and the rôle of "vital force" was being successfully restricted almost from day to day. Liebig pointed effectively to the fact that sugar undergoes other kinds of fermentation than alcoholic, such as lactic and butyric, but that nothing like a yeast organism was to be seen in these allied types of decomposition. It seemed to him that these various kinds of decomposition had one feature in common, the presence of a small quantity of nitrogenous substance. This dead material operated as the real ferment, by communicating a kind of shock to the molecules of sugar or beef extract with which it came in contact, which resulted in the fragmentation of the molecule into smaller molecules, the essence of fermentation and putrefaction.

To Pasteur the position of Liebig was wholly unintelligible because it rested on prejudice much more than on experimental evidence. He resolved to investigate the subject of fermentations from the standpoint which he had reached by observing the fermentation of the paratartrates —that is to say with the preconceived idea that fermentation depends on the mediation of living organisms. The first notable paper in the long series which solved one of the most pressing questions in biology deals with lactic acid fermentation.* It might perhaps have been anticipated that Pasteur's first important utterance on the nature of fermentation would deal with the alcoholic form which has so great a commercial importance. He discovered, however, in lactic fermentation an admirable field on which to contest the ideas of Liebig and his followers, who were constantly pointing out that in lactic fermentation, so like the alcoholic form, there is nothing at all like a yeast ferment. This research ended, as is well known, in the discovery of a specific lactic acid organism or ferment, and in the cultivation of this and other organisms in an artificial medium free from albuminoids. Pasteur was not slow in forming the hypothesis that different types of fermentation are dependent on different types of micro-organisms and this idea of specificity, soon established in relation to the ordinary de-

*During the years 1858 and 1859 Pasteur did highly important work on alcoholic fermentation. His views as to the significance of molecular dissymmetry had already led him to regard the levorotary action of amylalcohol as an indication that this regular product of alcoholic fermentation is found by the mediation of living organisms. It was in fact his study of amylalcohol (1855) together with the experiment on inactive ammonium paratartrate that incited Pasteur to undertake researches on the method of fermentative processes. His superior chemical training under Dumas was used to great advantage in all the researches on fermentation. In the case of alcoholic fermentation Pasteur showed that the acid formed is neither acetic nor lactic acid but that succenic acid and glycerine are regular and not unimportant products. Lavoisier and Gay-Lussac represented the sugar in alcoholic fermentations as splitting wholly into alcohol and carbon dioxide, but the work of Pasteur showed that five or six per cent. of all the sugar is not decomposed in this way.

compositions, ultimately became the basis of our modern knowledge of the infectious diseases.

The research on lactic acid fermentation thus gave the *coup de grâce* to the chemical theory of fermentation at the same time that it marked the birth of the promising science of bacteriology. The development of a method designed to secure pure cultures from fluid media, the use of culture media of known composition and the careful chemical study of products of decomposition, all belong to this early period of Pasteur's life and were achievements of the deepest significance for the future of the great department of knowledge which has revivified the biological sciences.

Another research on fermentation deserves more than passing notice on account of the extraordinary discovery which appears as its almost acidental by-product. This is the investigation on butyric acid ferments (1861). This research brought to light the fact that there are motile organisms capable of inducing a decomposition of sugar with the production of butyric acid. In the course of this research Pasteur saw that these organisms (whose motility was most puzzling on account of its suggesting animal life) behaved very differently according to their position with reference to the cover glass, those at the center being active, while those at the periphery and exposed to the air were checked in their movements.* From this casual observation came the fundamental conception of anaerobic life. All physiologists recognize to-day "A class of beings possessing such vigorous respiratory power," as Pasteur aptly says, "that they are able to live without the influence of the air by taking oxygen from certain compounds, thus occasioning in the latter a slow and progressive decomposition."

That Pasteur's original and searching examination of the problem of fermentation would one day lead him into a controversy over the unsettled question of spontaneous generation might almost have been predicted. The long discussion with Pouchet and Bastian, containing something of bitterness and not a little of the ridiculous, is a dramatic and animated chapter in the life of a peaceable but truth-loving man. As students of the influence of Pasteur on medical science we need not pause to review this controversy, for its fruits are to be found in all his subsequent work on the specific nature of the infectious diseases. Yet this discussion, prolonged over nearly twenty years, and replete with instruction and entertainment, is worthy of a permanent place in the memories of scientific men.

After a public victory over Pouchet in 1862, which brought in its train the honor of election to the Academy of Sciences, Pasteur turned his attention toward two subjects of much practical interest which seemed closely connected with the phenomena of fermentation. One of these was the manufacture of vinegar, the other the diseases of wine. The study of vinegar led to the recognition of the micro-organic nature of the vinegar film or mycoderma and brought acetic fermentation into line with lactic and butyric fermentations. It led also to the discovery that the oxidation of alcohol through the agency of the vinegar organisms may be carried too far, acetic acid being lost by oxidation to water and carbon dioxide. Then again Pasteur was able to aid the makers of vinegar by teaching them that the indispensable film formation can be facilitated by the actual transfer of the living ferment to the surface of the vinegar. In the study of the diseases of wine Pasteur achieved even more helpful practical results, for after recognizing the dependence of sour, bitter and muddy wines on the presence of definite types of living ferments, he was able to suggest a simple and efficient way of controlling these disturbing agencies by the use of moderate heat. From this recommendation has sprung the use of the widely employed method of sterilizing which we call Pasteurization.

In Pasteur's growing interest in these works of practical utility we can detect a tendency which was destined to bear rich fruitage in medical science—the inclination to employ the gifts of which he could no longer fail to be conscious in a manner likely to be directly helpful in relieving the needs of his fellow men. It was this attitude which made it possible in 1865 to lead Pasteur not without regret away from his studies of fermentation, to a wholly new sphere of endeavor. In that year the mortality among the silkworms of northern France was so great that the silkworm industry was threatened with total extinction and grievous famine was making its appearance in a land where comfort and contentment had long reigned. Dumas, acting for a senate committee, selected Pasteur to solve the mystery of the plague. To Pasteur's remonstrance that he knew nothing of the subject and had never seen a silkworm, Dumas answered, "So much the better, you will not have any ideas except those that come to you through your own observations." There were many unfriendly comments on this appointment, for some scientific men could not understand why a chemist should be chosen to cope with an obscure zoological problem. But Dumas knew his man and confidently relied on the great gifts he saw in him. It was quickly evident that his faith was not misplaced. Only twenty days after his arrival at Alais, Pasteur prepared a note in which he outlined a method of breeding from the eggs of silkworms free from disease. Unlike his predecessors, he made the moth the center of the efforts to regenerate the race of silkworms. "If the butterfly is sick reject all its eggs." It required five years of Pasteur's most devoted attention, five years beset with uncertainties and disappointments, to establish this almost clairvoyant conception on an incontestable scientific bass. At the end of this period Pasteur and his highly skilled assistants had shown that there were two distinct diseases from which the silkworms died, pébrine or corpuscle disease, and flâcherie, a bacterial affection of intestinal origin. The former was

*Pasteur fell into the error of describing the butyric acid organisms as infusorians and thought he had shown that animal life can exist without oxygen.

proved to be a specific disease due to the psorosperm *Nosema bombycis;* the latter was believed by Pasteur to depend on a specific bacterium, but can probably be excited by several distinct varieties of bacteria. The pébrine disease, which was the chief scourge of the industry, was eradicated through the use of a careful system of breeding from eggs shown by microscopical examination, to be free from infection. The immense practical importance of this method sociologically as well as financially can be better left to the fancy than expressed in dollars and cents. But these immediate practical results do not adequately express the far-reaching effects of the great silkworm research which marks the entry of Pasteur into the realm of animal pathology, and is thus the vestibule of modern medicine. For it is true that the laws governing the propagation and development of the flâcherie disease have the most striking analogies to those of the diseases of man. The varying susceptibilities of different individuals to the same micro-organisms, the influence of the path of infection and the fact that flâcherie organisms acquire increased virulence after passage through the bodies of living silkworms foreshadow discoveries in human pathology. The two volumes dealing with the diseases of silkworms and dated 1870 are works whose contents should be familiar to every independent student of the infectious diseases.

The researches on the silkworm diseases had one practical effect of considerable importance for Pasteur's later career. The success with which Pasteur had solved his intricate and widely known problem made it natural that French investigators of animal pathology should in future turn to him as the man most likely to help them in their work, and this brought to him new opportunities for fresh successes.

It is likely that excessive work and mental stress in some degree contributed to the onset of the series of paralytic seizures which in October, 1868, threatened the life of Louis Pasteur. During the critical period of his illness many of the most distinguished scientific men of France vied with each other to share with Mme. Pasteur the privilege of nursing the man they loved so well, and of rescuing the life that had already placed science and a nation under enduring obligation, through discoveries which were either of the greatest practical utility or appeared susceptible of almost unlimited development. Had Pasteur died in 1868 he would have left a name immortal in the annals of science. Others would in some degree have developed his ideas. Already inspired by the researches of fermentation, Lister would have continued to develop those life-saving surgical methods which will forever be associated with his name. But we may well question whether investigations in biology and medicine would not have been, for a time at least, conducted along less fruitful paths. Who shall say how soon the great principle of experimental immunity to pathogenic bacteria, the central jewel in the diadem of Pasteur's achievements, would have been brought to light?

When Pasteur recovered sufficiently to resume work it was soon clear to apprehensive friends that he had no intention of leaving his ideas to be worked out by other men. The miseries of the Franco-Prussian war deeply affected him, and could not fail to inhibit his productiveness, but after a time the unquenchable love for experimental research was once more ascendant, and there began a new epoch, the epoch of great discoveries relating to the origin and cure or prevention of the infectious diseases of man and the domestic animal. As in the case of Ignatius Loyola, it seems as if the lamp of genius shone with a larger and more luminous flame after the onset of bodily infirmity, in defiance of the physical mechanism which is too often permitted to master the will.

The hostility of Pasteur to Germany and all things Teutonic was greatly intensified by the events of the Franco-Prussian war and has left a somewhat regrettable impression on his scientific work. Desiring to contribute to the rehabilitation of his unhappy country he was led to improve the processes of brewing, with a view to increasing the wealth of France and at the same time lessening the yearly tribute to the despised people beyond the Rhine. It was easily shown that some of the diseases of beer are due to the action of bacteria allowed to take part in the process of fermentation. But it soon became clear that the mere exclusion of these micro-organisms does not insure a brew of good beer. The problem was considerably complicated by the difficulty of deciding what constitutes excellence in beer and this situation was not helped by the fact that Pasteur who disliked the German drink almost as much as he disliked Germans, could not distinguish one brew from another. Nevertheless, after many discouragements he succeeded in establishing methods which much improved the character of French beers, methods involving the aeration of beerwort by sterilized air and the abandonment of open coolers. The results were far from satisfactory owing to the circumstance that Pasteur quite overlooked the part played by the undesirable forms of yeast—so-called wild yeasts—in the production of abnormal fermentations. In fact it is doubtful if he could have separated the different types of yeast by the methods at his command, for even in so late a work as the famous "Etudes sur la Bière," bearing the date 1876, we are struck with the inadequate character of Pasteur's devices for obtaining pure cultures of micro-organisms.

This work with its tender dedication to the memory of Pasteur's father, was a highly important contribution to bacteriology in spite of its many botanical defects. It is really a bacteriological potpourri bringing together the writer's views on many questions, rather than a strict treatise on the diseases of beer. Besides chapters on the causes of bad beer and our improved methods of brewing, the volume treats of the origin of fer-

ments and furnishes conclusive experimental evidence against that plastic doctrine of the transformation of species around which the friends of the spontaneous generation fallacy were hopefully rallying. But by far the most striking and original chapter in this notable volume is that in which Pasteur formulated his physiological theory of fermentation—the startling theory that the essential characteristic of fermentation is life without air, life without free oxygen. This theory, if not entirely upheld by other biologists, has at least proved a powerful stimulus to new studies of this unexplored aspect of life.

Pasteur's life was prolonged a quarter of a century after the close of the war with Germany and during a large part of this long period his mind dwelt almost unceasingly on two phases of the great biological and practical problem which it was his fortune to develope so fruitfully. One of these was the investigation of the etiology of disease as related to the activity of micro-organisms. The other was the experimental study of the amazing phenomena of immunity to the action of specific viruses or virulent micro-organisms. These two interdependent phases of bacteriological research culminated in one of the most remarkable discoveries of all time, remarkable for its practical results but even more striking as an example of the use of the imagination in science. It is well worth while to consider the chief events that ultimately led to the discovery of a method of immunization against the virus of hydrophobia.

The idea that some diseases are due to living micro-organisms was suggested by Boyle two hundred years before the days of bacteriology. From time to time thoughtful men took up this idea as worthy of discussion but it received no substantial confirmation until Schoenlein, with the aid of the microscope made his admirable discovery of the infectious nature of ringworm. This was in 1839. Within a few years Henle, the gifted anatomist of Göttingen, proposed an ingenious explanation of the infectious diseases which assumed the agency of micro-organisms, but the theory though based on thoughtful clinical considerations was deficient in experimental data and had little practical influence on medicine. It is scarcely surprising that the leading scientific minds of the epoch should have been hostile to any mere hypothesis of contagion by germs, for in their struggle against the ancient conception of a vital force they regarded the idea of a *contagium vivum* exactly as Liebig had regarded Schwann's and Pasteur's doctrine of fermentation. Even the illuminating cell doctrine of Virchow was not especially favorable to the idea that living organisms from outside can excite disease by fixing themselves and developing in the body. Pasteur's training and temperament and genius admirably fitted him not merely to detect the great central truth of etiology but to force it, in spite of stubborn opposition, upon a doubting world half stunned at the boldness of the new doctrine. But while he took by far the larger part in compelling this revolution in the conception of disease the way was prepared by others, and especially by the fine observations of the biologist Casimir Joseph Davaine and the accurate and ingenious experimental methods of Robert Koch.

Davaine, while assisting the clinician Rayer in the study of the devastating anthrax plague in 1850 observed little thread-like bodies in the blood of animals dead of this disease. Ten years later Delafond observed these little threads to be living organisms with the power of multiplying outside the body. Thirteen years after his first observations Davaine, incited by Pasteur's suggestive work on the butyric acid ferment, reopened his study of anthrax and confidently proclaimed that the organisms he had found were the cause and the only cause of anthrax. But it required the superior technic of Koch unquestionably to obtain the anthrax organisms in pure culture, to follow the cycle of their development in the animal body and thus to place the important discovery of Davaine on an impregnable scientific foundation. Pasteur, entering this field a little later, independently worked out some of the most striking features of the etiology of anthrax and convinced the best scientific minds of France of the relationship between the bacilli of Davaine and the perpetuation of the anthrax plague.

Very closely associated with Pasteur's work on anthrax is the admirable research in which the master, aided by Joubert and Chamberland, discovered the organism known to us as the bacillus of malignant edema but described by its detectors as the *Vibrio septique* in the same year (1877) in which the widely known publication on anthrax appeared. Of the many excellent features for which this research is distinguished there are two that deserve especial mention. First, the recognition of the *Vibrio septique* in the blood of animals not newly dead of anthrax was an extremely important service in clearing up the gravest objections to Davaine's doctrine of the etiology of anthrax. Secondly, the observation that the septic vibrio is anaerobic affords the earliest example of a pathogenic organism which in its vegetative form is inhibited by the presence of oxygen—a discovery which we may reasonably attribute to the experience gained sixteen years before with the butyric ferment.

In looking for fresh proofs of the bacterial origin of disease Pasteur made some visits to the hospitals of Paris and thus came into closer relations with the practitioners of medicine and surgery. The alert and intellectually honest minds bade him welcome and gave him every help to pursue his studies; the conservatives looked at him askance, confidently set up their time-worn theories against his experimental proofs and lost no occasion to ridicule the germ theory of the origin of disease. To-day it is difficult for us to picture the incredulity and amazement of many prosperous and self-satisfied practitioners on hearing Pasteur's announcement that he had found the same pus exciting micro-organisms (probably the *Staphylococcus pyogenes aureus*) in the pus from a series of boils and in the pus from osteo-

myelitis, and that these conditions, so different in clinical characters are identical as regards etiology. Very soon a second bomb of the same nature fell into the conservative camp with the confident and even fervid declaration that childbed fever is a septicemia commonly due to a coccus (streptococcus)* which could be detected in the cavity of the uterus, in the blood of the uterine sinuses, and in the blood of living patients. The far-reaching practical results of this investigation, to which Pasteur devoted only one short publication, are so well known to you that they call for no comment here.

Not long after the beginning of the anthrax study the attention of Pasteur was directed to a disease which was destined to play a remarkable part in leading to the great goal toward which the researches of the master were carrying him—the discovery that it is possible experimentally to induce immunity to disease caused by virulent micro-organisms. Perroncito, of Turin, and Toussaint, of Toulouse, had reached the conclusion that an organism detected by the former is the cause of chicken cholera, but neither had the requisite bacteriological training actually to establish the correctness of this contention. Pasteur was consulted on the subject, and, bringing to bear his superior knowledge and technical skill, succeeded in growing the organism outside the animal body and in experimentally inducing chicken cholera by means of these cultures grown *in vitro*. Returning to the laboratory after a short absence he found that his cultures of the bacilli of chicken cholera had failed to grow or had grown only feebly. To increase the activity of these micro-organisms they were now inoculated into normal fowls—a procedure suggested by previous experiments with other bacteria. The results were disappointing, for the inoculated animals showed no signs of the disease. This made it necessary to isolate and grow actively pathogenic bacteria from animals with chicken cholera. Having done this it occurred to Pasteur that it would be of interest to inoculate with fresh and virulent bacilli the animals already treated with the attenuated strain of chicken cholera organisms. This was done without delay, and, to his surprise, nearly all of these prepared animals resisted the virulent germs. They had been immunized by means of the attenuated cultures and a new principle had come into medicine. By experimental study and long reflection on the work of Jenner, the mind of Pasteur had been prepared to grasp the immense practical significance of this discovery. It appeared probable that what had been accomplished for chicken cholera could be extended to other diseases. One special consideration made Pasteur feel hopeful as to the possibility of immunizing sheep and cattle against anthrax. He had noticed that certain sheep long exposed to anthrax through grazing on infected pastures did not die after experimental inoculation with a virulent anthrax culture, whereas previously unexposed animals of the same herd died promptly after such inoculation. Moreover, he knew from experience that fowls can be immunized against chicken cholera by feeding them the specific germs of that disease and this fact strongly suggested a similar explanation for the anthrax immunity which he had noticed. With that analogy in mind Pasteur took the first step toward the preparation of a vaccine against anthrax. As in the case of chicken cholera, he strove to attenuate the specific organisms of the disease. This he tried to do in the way that had succeeded so well in the case of chicken cholera, this is by exposing anthrax cultures to an abundance of oxygen at the body temperatures. But Pasteur found that under these conditions the anthrax organisms retain their virulence, owing, he believed, to their capacity to produce resistant spores. To check this growth of the anthrax spores he successfully resorted to the procedure of growing his cultures at a temperature of 42° to 43° C. in the presence of oxygen. By varying the procedure somewhat he was able to prepare a series of anthrax vaccines of different degrees of activity, the use of a mild vaccine being followed by that of a stronger one in the course of immunization.

The announcement by Pasteur, Chamberland and Roux of a method of protecting animals against the anthrax scourge excited great public interest but was in many quarters received with skepticism and derision. Pasteur was invited to make a large scale public test of his claims near Melun at the farm of Pouilly le Port. He accepted the challenge gladly and on May 5, 1881, began a series of public inoculations which will always be memorable in the annals of medical science. The publicity with which the unique experiment was performed; the unconcealed hostility and suspicion of many of the onlookers, and the alternating hopes and fears of Pasteur, have been most entertainingly described by M. Vallery-Radot. The outcome was a convincing demonstration of the practicability of Pasteur's method of immunizing against anthrax in sheep. Nevertheless, two years later, in an ill-natured attack on Pasteur's work, Koch attributed the discovery of vaccination against anthrax to Toussaint and pointed to a paper in which the latter had reported some experiments describing the immunization of dogs and sheep by means of anthrax bacilli which had been heated at 55° C. for ten minutes.

While it is true that Toussaint thus immunized animals against virulent anthrax organisms, his method of obtaining a vaccine was unreliable and unsuited for practical use. The fact is that Toussaint, stimulated by Pasteur's discovery of a method for immunizing against chicken cholera, prepared a vaccine which sometimes protected against the disease but which was dangerous owing to uncertainty as to the number and condition of the living anthrax organisms which it contained. His publication appeared six months after

*Pasteur's description of the organism found in puerperal septicemia is not full enough to make it certain that he was dealing with pure cultures of the *Streptococcus pyogenes*.

that of Pasteur, who, although greatly interested in the observation of Toussaint, criticized the methods of the latter and ultimately prepared a safe vaccine consisting of definitely attenuated anthrax organisms. The crude experiments of Toussaint were wholly based on the epoch-making immunization to chicken cholera originated by Pasteur.

On March 15, 1882, Louis Thuillier, the earnest and gifted but ill-fated young assistant of Pasteur, discovered in the blood of swine dead of erysipelas (rouget de porc) an organism which appeared to be the active agent of this plague—an organism which Klein in his elaborate investigation had quite overlooked, but which was independently discovered by Detmers, of Chicago. Pasteur had inspired this fine research of Thuillier and stood ready to develop it. By carrying the suspected organism through many generations on veal bouillon and finally introducing it into hogs, the true swine erysipelas was readily induced. The real problem, however, was to make an attenuated virus for the purpose of immunizing against the disease. Pasteur succeeded in obtaining a virus capable of protecting certain races of hogs for a period of a year or more and this important practical success is rendered especially noteworthy by the method that was followed in attenuating the rouget organisms. In 1887 he had found in the saliva of rabid dogs an organism highly virulent for rabbits, (micrococcus of rabbit septicemia).* Adult guinea-pigs were immune but young guinea-pigs quickly died after inoculation. By passing the organism through a series of young guinea-pigs it gained in virulence until it grew fatal for adult guinea-pigs. But the modification which especially impressed Pasteur was that the bacteria which had thus gained in pathogenic qualities for guinea-pigs had at the same time become attenuated for rabbits.

The memory of this singular observation now came to his aid in the rouget research. After passing the rouget bacteria through a series of pigeons (which are naturally susceptible) it was found that the blood from the last pigeon had become much more pathogenic for swine than blood from hogs dead of swine erysipelas. On the other hand, Pasteur discovered that while the passage of the rouget organisms through a series of rabbits (which are not naturally susceptible) permitted these bacteria to grow more readily in the blood of rabbits and to become more highly pathogenic for them, they became definitely and permanently diminished in virulence for swine. Thus after inoculation with modified organisms hogs became ill but did not die. On their recovery they were immune to fatal rouget. The genius of Pasteur thus gave to biological science a definite method of permanently modifying the pathogenic characters of certain micro-organisms. This contribution is recorded in a paper which won the applause of the Academy of Medicine and which even to-day excites admiration for its mingling of experimental skill and scientific imagination.

So far back as 1880, in the midst of the exacting anthrax investigation, Pasteur had found time to begin a new research on the protective action of attenuated virus. From modest beginnings this research grew in the hands of the master to be the crowning work of his life, in the sense of embodying the fullest and in some respects most original expression of his ideas on the use of experimentally enfeebled viruses for the mitigation of infectious processes. The transmission of rabies through bites made probable the infectious nature of the disease and encouraged a hope that it would not be very difficult to isolate the specific organism from the saliva of rabid dogs. But the most systematic efforts to isolate such an agent were rewarded only by failure. To this disappointment was added a second, even more disconcerting. It was found that the experimental transmission of the disease by means of saliva is a matter of great uncertainty. Moreover the uniformly fatal outcome of hydrophobia made it impossible to form any opinion as to whether the unknown virus was capable of conferring immunity. Many an investigator would have been deterred from the prosecution of an enterprise so unpromising, but the interest of Pasteur had been fully enlisted before he realized the difficulties of the problem, and the tenacity of his nature urged him to keep patiently on his course. He saw clearly that a reliable way must be found to communicate rabies experimentally and acting on a suggestion made by Dr. Dubu, of Pau, that the disease is essentially one of the central nervous system, Pasteur took small bits of nervous tissue from animals dead of rabies and placed them under the skin of experimental animals. This method was no considerable improvement on similar inoculations of saliva from rabid dogs, but it served as the clew to a notable advance. This was the introduction of rabic nerve-tissue directly into the central nervous system of the animal to be infected, a procedure based on the idea that since rabies behave like a disease of the nervous system the micro-organisms causing it would be likely to find in the nervous system a living culture medium highly favorable to their growth. The acute intelligence of the masterful experimentalist is strikingly illustrated by the fact that failure to isolate specific micro-organisms had not shaken his faith in the trustworthiness of his preconceived idea. Hence when he found that hydrophobia regularly followed subdural inoculation with rabic nervous material he was more pleased than surprised. The first dog thus inoculated showed unmistakable signs of rabies after fourteen days and other animals gave similar results. Moreover, on bringing into practice the experience he had gained in studying swine erysipelas, Pasteur found that he could increase the pathogenic properties of the virus by carrying it subdurally through a series of rabbits or reduce it for dogs by carrying it subdurally through a series of monkeys. He thus had at his command three different viruses, a

*Micrococcus lanceolatus.

virus of natural strength, a virus of increased virulence and an attenuated virus. Later experiments showed that a safer virus could be prepared by drying over caustic potash at 21° C. spinal cords of rabbits dead of rabies.

By injecting subcutaneously first a weak virus and subsequently a stronger one into parts with very few nervous structures Pasteur succeeded in immunizing dogs against otherwise fatal subdural inoculations. This success suggested the possibility of immunizing human beings. The relatively long duration of the period of incubation, which is commonly about forty days, made the outlook for human immunization peculiarly promising. The opportunity for trying the method soon appeared in the person of the little Alsatian lad, Joseph Meister, who came to Paris with fourteen wounds inflicted by a rabid dog. Pasteur courageously resolved to make an effort to rescue the bitten child from the certain death to which he was doomed, by making successive injections of rabbit viruses of increasing strength. The result is known to all the world; the effort to utilize the long period of incubation to quickly establish immunity through repeated inoculations, proved a success, not only in the case of little Meister, but in many thousand other instances.

The great research on rabies fittingly marks the culmination of Pasteur's long career as an investigator. In that investigation can be seen the same technical skill, the same respect for minute detail and the same pertinacity that had distinguished so many earlier researches, but there can be seen also a degree of originality and a fertility of resource that excel nearly all previous exhibitions of these powers. The accumulated experience of a quarter century of original study of micro-organic life served as intellectual capital on which Pasteur drew for guidance at every turn in the extraordinarily intricate and perplexing study of rabies. And it seems wholly clear that this new discovery could never have been made without such a treasure of experimental experience.

One who looks only at the results of Pasteur's far-reaching work is apt to overlook his mistakes and shortcomings and to forget that he made some serious errors not only in the interpretation of experimental data but sometimes also in experimental technic. To pathologists of the present day Pasteur's conception of acquired immunity appears so crude that it is difficult to believe he ever entertained it seriously. His work on chicken cholera naturally led him to form a theory to account for the immunization which he observed and this theory was that immunity arises from the inability of a pathogenic organism to grow in a medium in which it has previously developed. Animals thus become immune because the necessary nutrient material for the multiplication of the specific organisms has been made up, just as an organism will after a time cease to grow *in vitro* in an old culture medium. It seems strange that he did not test this theory by trying to grow the organisms outside the body in the blood and serum of both the immunized and normal animals and so learn that he was in error. The short and usually inadequate descriptions of micro-organisms which Pasteur has given in his terse publication have aroused much criticism from bacteriologists and it cannot be denied that he underrated the importance of minute morphological and cultural studies, studies without which some of the most important modern advances could not have been made. Nor is it easy to explain the reluctance with which he adopted the improved bacteriological technic of other investigators. Koch's method of plating bacteria, Weigert's and Ehrlich's methods of staining and certain important nutrient media found their way into his laboratory only after long delay and through the efforts of assistants. Pasteur's comparatively faulty technic for obtaining pure cultures of bacteria is doubtless responsible for many of the disheartening results reported by foreign observers who used his vaccines. Nevertheless his methods in the main served their purpose well, and we should remember that the most finished instruments cannot belong to the pioneer who makes his own tools. Fortunately, Pasteur was greatly favored by the circumstance that in many of his etiological studies he made cultures from the blood, where the specific micro-organisms often existed in pure culture.

Although even the plainest narrative of Pasteur's individual achievements is proof enough that his work holds a unique position in the history of biological science it is worth while to consider in more general terms what it was that the consummate experimentalist added to the science of medicine. Such a consideration gives us a more just measure of his influence than the most detailed recital of specific investigations. If we would understand the influence of Pasteur on medical science we must recognize that his example as the apostle of an almost untried method of approaching the problems of medicine has been no less enlightened than his actual discoveries. Emerson has said, "Great men exist that there may be greater men." The recent history of medicine in the United States as well as in Europe plainly shows that the seed of example sown by Pasteur has already fallen on receptive soil from which have sprung new combinations of human faculties powerful for the amelioration of human life. Our country has no greater cause for satisfaction than the knowledge that the ideality as well as the methods of Pasteur have inspired a growing circle of original investigators in medical science who labor for the common welfare. Let us hope that this circle will be continually widened, in the future as in the past, by accessions from the students of this University, where the best ideals of work have been so richly nurtured.

Perhaps the most deeply significant feature of Pasteur's contributions to medicine is their direct dependence on the principles of physics and chemistry, the sciences that so often lie at the heart of real advances in biology. Medical men

trained along the conventional semi-scholastic lines had often dabbled with these fundamental sciences and sometimes the superficial contact had yielded creditable or even important results. In many instances also truly great advances had come from the labors of men who like Malpighi, Bichat and Johannes Müller were wide awake to the fact that sound medicine must rest on sound biological conceptions.

But despite the activity of numerous gifted medical men of broad scientific sympathies the medical profession at the beginning of Pasteur's career was dully following a well trodden but nearly blind road, in the hopeless struggle to solve the intricate problems of human pathology and physiology by minute observations and experiments confined largely to the most complex representatives of animal life. Then for the first time there appeared in the biological sciences a man profoundly trained in the methods of chemistry and physics and inspired, moreover, with a firm confidence in the applicability of these sciences to the solution of biological and medical problems. Triply armed with a sound method, a lofty imagination and a strong will to serve his country, Louis Pasteur entered the wide arena of medical research, to win there the triumphs that have reconstituted medicine and have secured him an undying fame. Step by step, with rigid logic and unfaltering determination, he passed from the early crystallographic discoveries to the new conception of fermentation and from this to the crucial discoveries relative to etiology and immunity for which the medical sciences had waited so long.

To have fought the long battle of life with unwavering constancy to the loftiest ideals of conduct, toiling incessantly without a thought of selfish gain; to have remained unspoiled by success and unembittered by opposition and adversity; to have won from nature some of her most precious and covert secrets, turning them to use for the mitigation of human suffering—these are proofs of rare qualities of heart and mind. Such full success in life did Louis Pasteur attain, and from the consciousness of good achieved, his noble nature found full reward for all his labor.

Of the children whom fortune has endowed with splendid gifts, there are few whose lives have affected so profoundly and so beneficently the fate of their fellows, few who have earned in equal degree the gratitude and reverence of all civilized men. Although not many can hope to enrich science with new principles, all of us may gain from Pasteur's life the inspiration to cultivate the best that is in us. Let us keep living in our memories the inspiriting words which the master spoke on the seventieth anniversary of his birthday: "Young men, young men; devote yourselves to those sure and powerful methods of which we as yet know only the first secrets. And, I say to all of you, whatever may be your careers, never permit yourselves to be overcome by degrading and unfruitful skepticism; neither permit the hours of sadness which come upon a nation to discourage you. Live in the serene peace of your laboratories and your libraries. First ask yourselves, what have I done for my education? Then, as you advance in life, what have I done for my country? So that some day that supreme happiness may come to you, the consciousness of having contributed in some manner to the progress and welfare of humanity. But, whether our efforts in life meet with success or failure let us be able to say when we near the great goal, 'I have done what I could.'"

REPORT UPON THE RESULTS WITH DIFFERENT KINDS OF PURE AND IMPURE MILK IN INFANT FEEDING IN TENEMENT HOUSES AND INSTITUTIONS OF NEW YORK CITY: A CLINICAL AND BACTERIOLOGICAL STUDY.*

BY WM. H. PARK, M.D.,
AND
L. EMMETT HOLT, M.D.,
OF NEW YORK.

[From the Rockefeller Institute for Medical Research and the Research Laboratory of the Department of Health, New York City.]

The work, of which the following is a report, is a part of an investigation into the production, transportation and feeding of cow's milk in New York City, which was undertaken in the summer of 1901, and which was extended over two years. The entire investigation contemplated an inquiry into the condition of farms such as were supplying milk to New York, the transportation of milk, its condition on delivery and its effect upon the children in tenement houses and institutions.

Observations upon the results of feeding cow's milk to healthy infants in tenement houses were determined upon, since in this way it was believed we could best study the problem under the conditions actually existing, and also avoid those influences met with in institutions which in themselves are so deleterious to infants. For comparison, however, a number of institutions were carefully studied during the summer of 1901.

The purpose of this investigation was to gather some facts upon the following points: (1) To make a comparison of the results of infant feeding in tenements in winter and summer; (2) to determine how far such results were affected by the character of the milk used, especially its original bacterial content, its preparation, and whether it was fed after heating or raw; (3) to see to what extent results were modified by other factors, such as the care the infants received and the surroundings in which they lived.

The clinical observations contained in this report were made by the following persons who were employed by the Rockefeller Institute: Drs. Eli Long, Mary E. Goodwin, Jane Berry, Alma Vedin, Mary Willets and Marie Grund. During the first season, J. S. Mabey was employed by the Institute, but during the second by Mr. Straus. There assisted in the work as volunteers, Drs. J.

* Read before the Association of American Physicians, Washington, D. C., May 12, 1903.

Sobel, Angenette Parry and Ford. Dr. Sobel reported for two seasons on a group of babies fed from the Good Samaritan Dispensary. To all of these workers the greatest credit is due for the thorough and conscientious way in which they did their work. They were most earnest and painstaking in obtaining as far as possible the facts desired, and much of the value of this report is due to their efforts. The bacteriological investigations were for the most part carried out in the Research Laboratory of the Health Department; but also, to a considerable extent, in the Carnegie Laboratory of the New York University. Drs. Letchworth Smith, Mary E. Goodwin, Katherine R. Collins and Rose A. Bebb carried out this portion of the work.

Observations were made during the summer of 1901, the winter of 1901-2, and the summer of 1902; during each of these seasons the different groups of infants were followed for an average period of about ten weeks. A considerable number were unavoidably lost sight of owing to removal with failure to leave address, and various other causes; but all others who could be kept under observation are included in the report. Excluding all imperfect records and those cases that were observed too short a time to admit of any deductions, there remain 632, of which 98 were observed during the summer of 1901; 211 in the winter of 1901-2; 278 in the summer of 1902, and 45 in the summer of 1903. This special group of 45 is included although the observations were made after the general investigation had closed.

The plan of investigation was that each of the workers should have a group of children, never more than 50, under personal observation. So far as possible the children were kept under the same general conditions as before. The weights were taken with great care by the physicians, at regular intervals in most cases. Nearly all of the infants were observed in their homes, to which regular visits were made twice a week for the entire period. One group of about 50 was observed by Dr. Sobel at the Good Samaritan Dispensary to which mothers came daily for the milk for their infants. When necessary one of his assistants went to their homes. In all cases advice was given in regard to matters of hygiene and the general care of the children. It was customary to stop the milk temporarily, whenever acute disturbances of digestion existed.

Bacteriological Investigation of the Milk Used in Feeding.—The clinical work was carried on in conjunction with a bacteriological study of the milk used, in order to determine whether any relationship existed between the number and character of the micro-organisms in milk, and the amount of diarrheal disease in the children to whom it was fed. Bacterial counts were made once or twice a week from the milk as given to each child. Specimens being taken at times from the raw and at times from the heated milk.

The bacteria were isolated from the milk through plating in a two-per-cent. lactose-litmus-nutrient-gelatin, or agar, and later grown upon the usual identification media. The pathogenic properties of the different bacteria were tested by intraperitoneal and subcutaneous inoculation in guinea pigs with 2 c.c. of a forty-eight-hour broth culture, and by feeding young kittens for several days with 3 to 6 c.c. daily of a twenty-four-hour broth culture by means of a medicine dropper.

With the characteristics of the bacteria thus determined, they were then separated into classes following as nearly as possible the lines suggested in Chester's Manual of Determinative Bacteriology. Further attempt was then made to identify as many as possible of the varieties with those previously described, using the descriptions of Chester and Migula. With a great many this proved unsatisfactory or impossible because of the incomplete descriptions in literature, or the lack of all description.

The varieties isolated represent only the species presenting greatest number in the milk examined, for in no case was more than 0.01 c.c. of a milk, and in most highly contaminated milks, only 0.001 c.c. used in making a plate, and varieties which occurred in too small numbers to be present in this quantity would necessarily be missed. For the purposes of this article it is not considered desirable to burden the reader with the enumeration of the varieties of bacteria found in the different samples of milk and their characteristics. Only a brief summary of the results will be given.

From the milks altogether 239 varieties of bacteria were isolated and studied. These 239 varieties, having some cultural or other differences, were divided into the 31 classes, each class containing from 1 to 39 more or less closely related organisms.

As to the sources of bacteria found in milk, we made sufficient experiments to satisfy us that they came chiefly from outside the udder and milk ducts.

Bacteria were isolated from various materials which under certain conditions might be sources of contamination for the milk, and the cultures compared with those taken from milk. Thus there were obtained from 20 specimens of hay and grass, 31 varieties of bacteria; from 15 specimens of feces, manure and intestinal contents, 28 varieties; from 10 specimens of feed, 17 varieties. Of these 76 varieties there were 26 which resembled closely those from milk, viz., 11 from grass or hay; 26 from manure; 5 from feed.

During the investigation a number of the varieties isolated from milk were shown to be identical with types commonly found in water.

From the few facts quoted above and from many other observations made during the course of the work, it would seem that the term "milk bacteria" assumes a condition which does not exist in fact. The expression would seem to indicate that a few varieties, especially those derived in some way from the cow, are commonly found in milk, which forms having entered the milk while still in the udder, or after its with-

drawal, are so well fitted to develop in milk that they overgrow all other varieties.

As a matter of fact, it was found that milk taken from a number of cows, in which almost no outside contamination had occurred, and plated immediately, contained, as a rule, very few bacteria, and these were streptococci, staphylococci and other varieties of bacteria not often found in milk sold in New York City; the temperature at which milk is kept being less suitable for them than for the bacteria which fall into the milk from dust, manure, etc. A number of specimens of fairly fresh market milk averaging 200,000 bacteria per c.c. were examined immediately, and again after twelve to twenty-four hours. In almost every test the three or four predominant varieties of the fresher milk remained as the predominant varieties after the period mentioned.

The above experiments seem to show that organisms which have gained a good percentage in the ordinary commercial milk at time of sale will be likely to hold the same relative place for as long a period as milk is ordinarily kept. After the bacteria pass the 10 or 20 million mark, a change occurs, since the increasing acidity inhibits the growth of some forms before it does that of others. Thus some varieties of the lactic acid bacteria can increase until the acidity is twice as great as that which inhibits the growth of streptococci. Before milk reaches the curdling point, the bacteria have usually reached over a billion to each c.c. For the most part specimens of milk from different localities showed a difference in the character of the bacteria present, in the same way that the bacteria from hay, feed, etc., varied. Even the intestinal contents of cows, the bacteriology of which might be expected to show common characteristics, contained beside the predominating colon types, other organisms which differed widely in different species and in different localities. Cleanliness in handling the milk and the temperature at which it had been kept were also found to have had a marked influence on the predominant varieties of bacteria present.

Pathogenic Properties of the Bacteria Isolated.—Intraperitoneal injection of 2 c.c. of broth or milk cultures of about 40 per cent. of the varieties tested, caused death. Cultures of most of the remainder produced no apparent deleterious effects even when injected in larger amounts. The filtrates of broth cultures of a number of varieties were tested, but only one was obtained in which poisonous products were abundantly present. Death in guinea pigs weighing, 300 grams followed within fifteen minutes after an injection of 2 c.c.; 1 c.c. had little effect.

As bacteria in milk are swallowed and not injected under the skin, it seemed wise to test the effect of feeding them to very young animals. We therefore fed forty-eight hour cultures of 139 varieties of bacteria to kittens of two to ten days of age, by means of a glass tube. The kittens received 5 to 10 c.c. daily for from three to seven days. Only one culture produced illness or death. A full report on the identification of the varieties of bacteria met with in this investigation can be found in an article by Dr. Smith in the 1902 Annual Report of the Department of Health.

After two years of effort to discover some relation between special varieties of bacteria found in city milk and the health of children, the conclusion has been reached that neither through animal tests nor the isolation from the milk of sick infants have we been able to establish such a relation. Pasteurized or "sterilized" milk is rarely kept in New York longer than thirty-six hours, so that varieties of bacteria which after long standing develop in such milk did not enter into our problem. The harmlessness of cultures given to healthy young kittens does not of course prove that they would be equally harmless in infants. Even if harmless in robust infants, they might be injurious when summer heat and previous disease had lowered the resistance and the digestive power of the subjects.

This failure to discover definite pathogenic bacteria, as well as the numerous varieties of bacteria met with, have forced us to rely on the clinical observation of infants to note what difference, if any, occurred in those fed on raw and Pasteurized milk from the same source, and upon different milks of unknown origin varying in the number of bacteria contained. In the following pages, observations upon food are combined with those upon other factors which influenced the health of the infants.

Selection of the Children for Observation.—The original aim was to include only infants who were entirely bottle-fed, but it was found that the great majority of all infants in the tenements receive during the first six months occasional breast feedings at night, and nearly all are given some solid food after they are six months old, or as soon as they are able to hold it in their hands. The purpose of the investigation being to obtain relative results with different forms of milk and not absolute results with one form, it is believed that the conclusions reached are not affected by the fact that many of the infants received breast feeding at night. Indeed including such infants has the advantage of studying representatives of a very large class. In each season some infants who were entirely breast-fed were observed for purposes of comparison.

In selecting the children the only conditions made were that they should not be ill or suffering from marasmus when observations were begun, and that they should be of suitable age. Of the entire number 340 were six months old or under, 265 were from seven to twelve months; 47 were a little over twelve months. With the exceptions stated, every child available was included by the physicians until the proper number was made up. The district in which most of the children lived was the lower east side of New York, as densely populated as any part of Manhattan Island.

An unexpected difficulty was encountered in beginning the investigation in the scarcity of bottle-fed infants in the region where the families were selected. One of the physicians reported

that in a densely populated neighborhood where every street was swarming with children, hardly half a dozen bottle-fed infants could be found on a block. While this may not have been true of the entire district, it was the observation of all the workers that the proportion of bottle-fed infants in tenement houses was surprisingly small. This is a very different impression from what one gains from visiting dispensaries where great numbers of bottle-fed infants are seen. But the dispensaries draw patients from very large districts and gather the cases that are not doing well, so that the aggregate seems very large. This excess in proportion of the bottle-fed infants at the dispensaries over that in the houses is in itself striking testimony to the advantages of breast feeding.

The Character of the Food Employed.—It was at first intended to make no change in the food the child was receiving, but it was found necessary in order that observations might also be made upon the comparative effects of heated and unheated milk in summer to place a number of infants upon a modified raw milk provided for them, which was a part of a larger supply distributed to others after Pasteurization. This was rendered all the more necessary since it was discovered that during the summer the sterilization of milk in some form was almost universally practiced in the tenements of New York. In the summer of 1902 especially, it was rare to find an infant fed upon raw milk; an incidental testimony to the value of the praiseworthy efforts of the Health Department, and the agitation in the public press in favor of clean milk and the necessity for sterilization in hot weather. When gastro-intestinal disturbance of any severity developed, the infants were deprived of milk for a day or two and put on barley water or other suitable food.

In the district where the observations were made the following forms of milk were extensively used: (1) Condensed milk; (2) milk purchased at small stores with groceries and other provisions and known as "store milk;" (3) bottled milk; (4) milk from central distributing stations, chiefly from the Straus milk depots and Good Samaritan Dispensary.

Condensed Milk.—That used was usually bought in cans, *i.e.*, the sweetened variety; seldom were the best brands purchased. It was generally prepared at each feeding by adding hot water which, in most cases, had been boiled.

Store Milk.—This is the poorest grade of milk sold in New York, but varies at the different stores. It is kept in large cans in the small stores and is sold to customers at an average price of four cents a quart. It averages about 3.75 per cent. of fat. It is customary for milk to be purchased twice a day and it is carried home and kept in pails or pitchers. In summer it is usually heated at once; if it curdles, it is considered to be unfit for use and is returned. During the hot days of the summer of 1901, it frequently happened that milk obtained from two or three consecutive stores would curdle. Heating is usually done in a saucepan and the temperature is raised to a point where the milk begins to "foam," seldom to a boiling point. In most cases it is kept upon ice. It is usually prepared for the infant at each time of feeding. The only modification practised is, in most cases, dilution with water or barley water, equal parts being as a rule given when infants are about three months old and continued until ten or eleven months when whole milk is given. The bacteriological examination made of this milk during the summer of 1901 showed it to contain from 4,000,000 to 200,000,000 microorganisms, an average of about 20,000,000 per c.c. The form of heating employed killed, it was found, about 95 to 99 per cent. of the bacteria present. In the summer of 1902, owing partly to the cooler season, but chiefly to the new regulations of the Health Department regarding the care and sale of milk, the average was about 3,000,000 per c.c. During the winter the number of bacteria ranged from 100,000 to 5,000,000 bacteria per c.c., and averaged about 400,000 per c.c.

Bottled Milk.—The greater part of the bottled milk used in these tenements was handled by one of the largest dealers in the city. This milk was produced under conditions which were only fairly good. However, it was so well handled during transportation and delivery that it was nearly always in good condition when received by the consumer. This milk averaged about 500,000 bacteria per c.c. It was sold in covered jars at eight cents a quart. The same general plan of modification was practised as with the store milk, and it was also in summer heated and usually in about the same way. As the people who purchased this were not so poor as those using store milk, they were more likely to use ice for keeping it.

Besides this bottled milk some special milk from the Walker-Gordon and Briarcliff Farms was furnished gratuitously to a limited number of cases for the sake of comparison but this was not widely enough used to admit of drawing conclusions sufficiently definite to be expressed in figures. This milk averaged about 10,000 bacteria per c.c.

Milk from Central Distributing Stations.—The greater part of this milk was supplied from the Straus Milk Depots of which there are a number scattered through the city, and from the diet kitchen of the Good Samaritan Dispensary, a small quantity from other diet kitchens. The milk used at these places was generally of excellent quality, usually from an "inspected" or "certified" farm, but it was mixed with poor cream. It was furnished gratis to those too poor to pay, and at a small charge, usually one cent a bottle, to others. This milk after the addition of cream averaged before Pasteurization nearly 2,000,000 bacteria per c.c.; after Pasteurization, about 500 per c.c.; after boiling, about 5 per c.c. It is supplied in small bottles, each one containing the quantity for a single feeding. The bottles are washed and sterilized at the central stations. The Straus milk

was generally Pasteurized; that from the Good Samaritan Dispensary was boiled. With both some attempt at modification was made, three or four standard formulas being used. The common modification consisted in the dilution with boiled water, the addition of lime water, milk sugar, and, in some cases, cream also; or the dilution with barley water and the addition of cane sugar. Regarding the use of these formulas, the quantity for one feeding, and the number of feedings daily, directions were usually given by the physicians in attendance at the Central Stations. As the mothers came daily for their milk, some constant supervision of the cases was thus possible, and many minor disturbances of digestion no doubt controlled by a proper variation in the food.

Infant Foods.—It was a surprise that the proprietary foods were so little used in the tenements, the expense being apparently the chief reason. Although they were given to a number of children observed, they were seldom used for a long time, or as the sole diet, and certainly cut no figure in the results. We have therefore not classified these cases separately.

Breast Feeding.—As already stated, the great majority of infants reared in tenements are breast-fed, at least for the first six months. No effort was made to collect many observations upon these children, but a few were introduced for the sake of comparison. It was thought at first to make a separate division of the children who were partly breast-fed, as it was the impression of some of the physicians who followed the cases that a decided difference existed between those who were partly nursed, usually at night, and those entirely fed. However, the general figures when tabulated did not show any very marked difference. The results seem to have depended rather upon the character of the other food.

In estimating the results obtained by the different methods of feeding two things were considered: first, the gain or loss in weight, and secondly, the amount of digestive disturbance, particularly diarrhea, which occurred in the different groups of infants. The cases have been divided according to results in four groups: (1) Those which did well. In this group are included the infants who made a substantial and generally a regular gain in weight during the period of observation, this usually amounting to from two to five pounds for the ten or twelve weeks, and those that had no diarrhea worth mentioning—usually both conditions existed together. (2) Those which did fairly, including those in which some diarrheal disturbance was present but not of a serious nor prolonged character, and in which the weight was either stationary or the gain very slight. Both these generally went together. (3) Those which did badly, including those in which considerable digestive disturbance, usually diarrhea, was present, or in which there was a loss in weight; generally here also both factors existed. (4) The fatal cases.

The following tables show in a condensed form the results obtained with the different foods employed in winter and in summer.

TABLE I. FOOD AND RESULTS.—WINTER.

	Did well.	Did fairly.	Did badly.	Died.	Totals
Store milk	47	6	2	0	55
Condensed milk	39	5	2	2	48
Good bottled milk	51	13	1	3	68
Milk from Central Distributing Stations	35	20	4	0	59
Best bottled milk	5	0	1	0	6
Breast feeding	7	1	0	1	9
Totals, excluding cases counted twice	156	41	8	6	211

TABLE II. FOOD AND RESULTS.—SUMMER.

	Did well.	Did fairly.	Did Badly.	Died.	Totals
Store milk	21	23	20	15	79
Condensed milk	22	20	14	14	70
Good bottled milk	37	23	29	9	98
Milk from Central Distributing Stations	84	33	24	4	145
Best bottled milk	9	3	0	0	12
Breast feeding	17	7	7	0	31
Totals, excluding cases counted twice	184	108	88	41	421

Season and Results.—Nothing could be more striking than the contrast between the results in winter and in summer. The general summary shows that of the 211 winter cases, 156 did well; 41 did fairly, 8 did badly and 6 died. In other words, what might be considered good results were shown in 93 per cent. of the cases, and bad results in only 7 per cent. Furthermore, in only one of the six deaths was the cause connected with the digestive tract.

Of the 421 summer cases, 184 did well, 108 did fairly, 88 did badly and 41 died. In other words, good results were obtained in 69 per cent. of the cases and bad results in 31 per cent. while in nearly all of the fatal cases death was due to diarrheal diseases. It should be remembered that all the children both winter and summer had the advantage of some continuous intelligent oversight, usually one visit a week and often two being made by the physicians. This supervision contributed in no small degree to the results in both groups of cases.

The difference in results in the summers of 1901 and 1902 was not great; the percentage of bad results in 1901 being 37; in 1902, 35 . This may have been due to the slightly cooler season of 1902, or the better general quality of the city's milk. The proportion of children on the different varieties of milk varied somewhat in the two years, so that a strict comparison is difficult.

The showing made by the winter cases is most gratifying and was indeed a surprise to all. So large a percentage of good results by all methods of feeding, and apparently so little difference between them was not expected. Artificial feeding in the tenements in winter would seem to be comparatively a simple problem.

To what shall be ascribed the great difference between summer and winter results? There seem to be many factors, but a consideration of the facts accumulated indicate that heat is the primary factor and bacteria and their products a secondary

one, except when the contamination is extreme or pathogenic organisms are present.

The effect of continued heat upon the health of infants is shown in the number of cases of diarrheal diseases and the number of deaths during ing the months of the summer of 1901 in an institution in the country near New York City, where a fairly pure milk was fed raw. During the winter and spring there was almost no diarrhea; with the warm weather of June it increased, reaching its highest point in August. The comparative results with the breast and bottle-fed infants are also evident.

Month.	No. of Infants.	Food.	Deaths.
June	34	Breast milk	0
	25	Cows' milk	0
	38	Breast and cows' milk	0
	128*	Milk and barley food	0
	Total..225		
	Number of cases of diarrhea, 15; deaths, 0.		
July	32	Breast milk	0
	20	Cows' milk	3
	38	Breast and cows' milk	0
	124*	Milk and barley food	0
	Total..214		
	Cases of diarrhea, 38; total deaths, 3 (all bottle-fed).		
August	28	Breast milk	0
	18	Cows' milk	3
	32	Breast and cows' milk	4
	129*	Milk and barley food	2
	Total..207		
	Cases of diarrhea, 50; total deaths, 9.		

Food and Results.—(1) Store Milk.—The largest number of bad results were seen, as was expected, with the cheap store milk, where not only was the milk poorer, but the care at home less. The winter observations upon this milk included 55 cases in about half of which some method of partial sterilization was employed; in the remainder it was given raw. Of these 55 infants, 47 did well; 6 did fairly; only 2 did badly and none died. Combining those who did well and those who did fairly, we have what may be considered good results in 96 per cent. of the cases and bad results in only 4 per cent. There was little apparent difference in results between those taking raw and those taking heated milk.

Store milk was the food of 79 of the summer cases. Of these 21 did well; 23 did fairly; 20 did badly and 15 died; in other words, good results in 56 per cent. of the cases, and bad results in 44 per cent. In nearly all of these cases the milk was heated in some way before feeding; usually it was raised nearly to the boiling point. This had the effect, it was found, of killing about 99 per cent. of the micro-organisms present, but the milk still contained after such heating between 5,000 and 500,000 bacteria to the c.c. An interesting point of tolerance of such milk was noticed in many cases. A number of infants living in bad surroundings, yet who received fairly good care, took only cheap store milk and yet remained well throughout the entire summer. During 1901 some of the store milk was very bad, averaging on hot days over 100,000,000 bacteria per c.c.

(2) Condensed Milk.—There were 48 winter observations upon infants taking condensed milk; 39 children did well, 5 did fairly, 2 badly, and 2 died, *i.e.*, good results were seen in 92 per cent. and bad results in 8 per cent. of the cases.

There were 70 summer observations made upon infants taking condensed milk. Only 22 of these children did well, 20 did fairly, 14 badly, and 14 died; or 60 per cent. good results and 40 per cent. bad results.

The results with condensed milk can hardly be attributed to the bacteria, inasmuch as it was almost invariably prepared with boiled water and contained relatively a small number of micro-organisms before heating. These children were often apparently in good condition until attacked with acute disease, when they offered but little resistance and seemed to succumb more quickly than any other class of patients. In one family three healthy infants, triplets, five months old, were taken sick on the same day with vomiting and diarrhea; one died within twenty-four hours, one within two days, and the third within a week. A bacteriological examination of the prepared milk remaining in one bottle showed nothing noteworthy.

(3) Bottled Milk.—The better results observed with bottled milk should not be put down as entirely due to the character of the food. The people who purchased it were seldom so poor as those buying store milk; they were usually more intelligent and probably more careful in handling the milk. Often they had ice.

There were 68 winter observations on children fed upon bottled milk; of these 51 did well, 13 fairly, only 1 did badly, and 3 died. None of these deaths were due to intestinal disease. In other words, there were good results in 94 per cent. of the cases, and bad results in 6 per cent.

There were 98 summer observations upon infants fed on bottled milk; of these 37 did well, 23 fairly, 29 did badly, and 9 died. In other words, 61 per cent. of good results and 39 per cent. bad results. In these quite a number received the milk raw, but as in the other observations, as soon as any illness occurred, some form of attempt at sterilization was almost invariably practised.

It is interesting to compare these results with those seen with store milk just above them in the table. The percentage mortality with the better grade of milk is only about one-half that seen with either condensed or store milk, and yet the large number of infants who did badly brings the proportion of bad results with bottled milk almost up to that with the two preceding varieties. It was noteworthy, however, that among infants included as doing badly there was on the average less sickness than among those fed on store milk. It would seem therefore that good bottled milk as now used, while much less dangerous to life than cheap store milk, is still, judging by this proportion of failures, rather unsuccessful as a method of feeding.

(4) Milk from Central Distributing Stations.—There were 59 winter observations upon these

* Those on milk and barley food were all over twelve months old.

patients, of which 35 did well, 20 fairly, 4 did badly and none died. In other words, good results in 93 per cent. of cases and bad results in 7 per cent.

There were 145 summer observations upon infants fed in this way; of these 84 did well, 33 did fairly, 24 did badly, and 4 died. In other words, 81 per cent. of good results, and 19 per cent. bad results. In about one-half of these cases the milk was Pasteurized; in the remainder, with the exception of a group of 42 cases to be mentioned later, in which the milk was given raw, the milk was sterilized.

The great difference between these results and those obtained with the three forms of feeding already considered deserves special attention. The original milk used at the stations was of good quality, but not much better than the bottled milk generally used; with both some form of sterilization was practised. The difference in results is not explained by the difference in these two factors. There were others of importance which must be sought. A certain amount of constant supervision was exercised over these infants, as some one, usually the mother, came daily to the milk dispensary for the food. Changes could thus be readily made in the milk according to the child's condition. If symptoms of slight indigestion were present, the mother was instructed to dilute the milk; with more severe symptoms, milk was temporarily stopped, etc. This supervision seems to us of the greatest value and can hardly be secured so well in any other way. Again, a mother sufficiently interested in her baby to come or send daily several blocks for the milk is generally one who values what she receives and also the advice which goes with it. This food, obtained in separate bottles for each feeding, is generally regarded by the tenement population as not exactly milk but as something very special, and therefore entitled to much more consideration than any form of food which they could prepare themselves at home.

Another point of importance is that some systematic attempt at milk modification was made in the milk furnished from central stations. Although this could not be done as accurately as for a smaller number of patients, the results were certainly improved by it. Again what contributed, in no small degree to success with this plan of feeding, was that this milk was supplied in separate bottles for each feeding, that the quantity for one feeding was suitable for the child, and that only a proper number of feedings for the twenty-four hours was dispensed at one time. There was not, therefore, the temptation to overfeeding and too frequent feeding, which with other methods are so generally practised. Finally, the bottles in which it was kept were always properly cleansed, and sterilized, since this was attended to at the central station.

(5) Best Bottled Milk.—This was furnished to 18 infants living in the tenements, to discover whether any perceptible difference existed between the results with this milk and the other varieties. While these observations are not numerous enough to admit of any generalizations, they indicate what was previously believed, that, with the cleanest milk from the best cared for cattle, the smallest number of bad results occurred.

There were 12 infants placed upon this milk in summer; of these 9 did well, 3 fairly, there were none who did badly and no deaths. There were 6 infants upon this milk in winter, of whom 5 did well and 1 did badly.

The difference between very bad, highly contaminated milk, like that purchased at some of the small stores previous to 1902 and the best bottled milk, was in some cases very striking. Protracted diarrhea in infants who were taking store milk was often immediately improved and in several cases promptly cured by simply substituting clean milk, after an interval of no milk, for the previous food. In some severe cases, however, no improvement followed the purer milk.

Age and Results.—In 17 cases the ages were not recorded. Of the summer cases 217 were infants under six months; 191 were between six and twelve months, and 47 were over twelve months. The comparative results for the different ages are shown in the following table.

TABLE III. AGE AND RESULTS—SUMMER.

Age.	Did well. Per cent.	Did fairly. Per cent.	Did badly. Per cent.	Died. Per cent.
Under 6 months.....	52	16	19	13
7 to 12 months.....	34	32	26	8
Over 12 months.....	49	32	19	0

Of the winter cases 123 were infants under six months, and 74 from seven to twelve months; none was over twelve months.

TABLE IV. AGE AND RESULTS—WINTER.

Age.	Did well. Per cent.	Did fairly. Per cent.	Did badly. Per cent.	Died. Per cent.
Under 6 months.....	74	21	0	5
7 to 12 months.....	70	20	10	0
Over 12 months.....	..	..	..	..

These figures indicate a considerably higher mortality in infants under six months, but a surprisingly large proportion of infants over this age who did badly. In summer, other factors than the milk used must be taken into account, one of the most important being the unwise giving of table food to infants over six months old, a practice which is almost universal in the tenement population. Giving fruits even to infants is also an important cause of illness. This was strikingly seen among the Italians. In this class of the population it was the opinion of some of the physicians who observed these cases, that the use of fruit, often unripe, stale or partly decayed, was the cause of more illness in infants and young children than the impure milk.

A separate study has been made of these cases which did badly, and the fatal cases, to determine any other factors beside the food and age which contributed to the results. An attempt was made to discover what sort of care these infants received, what their surroundings were, and whether the results in feeding were due to con-

ditions or diseases entirely outside the digestive tract.

Cases Doing Badly.—There were 96 infants who did badly, *i.e.*, they lost weight during the period of observation and had more or less disease of the digestive tract. Eighty-eight of these were summer cases and 8 were winter cases. The previous condition of this group of infants does not throw any special light upon results. This is noted in 86 of the 96 cases. In 52 the previous condition was put down as "good," and in 30 as "not good." It should be remembered that no infants previously in bad condition were included in the observations. The proportion of "good" and "not good" is about the same as in the children taken as a whole.

Care.—In the 88 summer cases this was not stated in 14; 30 were reported as receiving good care, 20 as having fair care, while 24 were positively neglected. The importance of the care the children received, as affecting the results of infant feeding, cannot be expressed in figures. What is included here as neglect was often of the grossest kind. As for example, where a mother was away all day at work and the infant left in charge of some old man, or irresponsible child, and where the visitor found bottles dirty, nipples rolling about the floor, sour milk in the feeding bottles, etc. It was practically the unanimous opinion of the physicians who made the observations that intelligent care had more to do with the results of feeding than any other factor. Many individual instances were reported of infants living under the worst surroundings and whose food was a very inferior kind of milk, and yet if the mother was intelligent and the infant well cared for, it throve in spite of the unfavorable conditions. On the other hand if the infant had no proper care it made little difference how good the milk furnished might be, the results were usually bad. One case will serve as an illustration. An Italian child two months old who had an intelligent, careful mother, did well for the entire summer on store milk. The following winter the mother was ill for a long time, during which time the child ran down steadily in spite of the fact that it was older and the weather was cold.

Surroundings.—While surroundings had a distinct influence upon the results in feeding, they were decidedly of less importance than the care. Since all these infants lived in tenements none could be said to have good surroundings. They were fair in 40 of the summer cases; distinctly bad in 33; in 15 they were not noted. Of the 8 winter cases, 7 had fairly good surroundings. By bad surroundings are meant very crowded apartments, rear tenements or basements. Many infants living in such places were rarely taken into the open air. Where the mothers availed themselves of the opportunities offered for day excursions upon the water and such fresh air as even the crowded city afforded, a distinct improvement was seen in the condition of the children.

Diarrheal Diseases and Other Forms of Acute Illness.—The number of days of diarrhea indicates pretty well the nature of the symptoms from which these infants chiefly suffered. Of the 88 cases which did badly, only 3 had no diarrhea; 19 had diarrhea lasting from one to seven days; 19, diarrhea from eight to fourteen days; 47, diarrhea of more than two weeks' duration. Other complications were present in 11 cases: bronchitis in 5; pertussis in 2; otitis in 1, and pneumonia in 3 cases. Of the 8 winter cases which did badly, none had diarrhea, but three had other complications, viz., one had measles, one bronchitis, and one pertussis.

Fatal Cases.—Of the 632 children observed, 47 or 7.5 per cent. died during the three months of observation. The mortality of the 211 winter cases was 2.8 per cent.; of the 421 summer cases, 11.3 per cent. Of infants under one year, neither in the age nor the previous conditions do we find any sufficient explanation of the fatal result. In the 47 observed who were over one year, no deaths occurred. The care which the fatal cases received is significant. Only 16 of the 47 infants who died received good care, and 19 were recorded as positively neglected. In 21 of the cases the surroundings were bad. The causes of death in the fatal cases were as follows:

Disease.	Summer.	Winter.
Diarrheal diseases	32	1
Pneumonia	5	2
Tuberculosis	2	0
Rickets	1	0
Diphtheria	1	0
Marasmus	0	1
Accident	0	1
Unknown	0	1
	41	6

The winter case having diarrhea was fed upon good bottled milk sterilized, and had gastric as well as intestinal symptoms. The marasmus case was a child fed upon condensed milk. In only two of the winter deaths could the result be definitely connected with the feeding; while in summer this was true of 30 of the cases.

Heated Milk vs. Raw Milk for Infants.—During each of the summers of 1902 and 1903, a special lot of milk was modified at one of the Straus depots for a group of 50 infants, all of whom were under nine months of age, and distributed daily in the usual way. To one-half the infants the milk was given raw; to the other half, Pasteurized.

The modified milk was made from a fairly pure milk mixed with ordinary cream. The bacteria contained in the milk numbered on the average 45,000 per c.c., in the cream 30,000,000. The modified raw milk taken from the bottles in the morning, averaged 1,200,000 bacteria per c.c.; the Pasteurized, about 1,000; taken in the late afternoon of the same day, they had respectively about 20,000,000 and 50,000.

Twenty-one predominant varieties of bacteria were isolated from six specimens of this milk collected on different days. The varieties represented the types of bacteria frequently found in milk. The infants were selected during the first week in June, and at first all were placed on Pasteurized milk. The 50 infants which had

been selected were now separated into two groups as nearly alike as possible. On June 15, the milk was distributed without heating to one-half the infants, the other half receiving as before the heated milk. In this way the infants in the two groups received milk of identically the same quality, except for the changes produced by heating to 165° F. for thirty minutes. The infants were observed carefully for three months and medical advice was given when necessary. When severe diarrhea occurred barley water was substituted for milk.

The first season's trial gave the following results. Within one week 20 out of the 27 infants put on the raw milk suffered from moderate or severe diarrhea; while during the same time only 5 cases of moderate, and none of severe diarrhea occurred in those taking Pasteurized milk. Within a month 8 of the 27 had to be changed from raw back to heated milk, because of their continued illness; 7 or 25 per cent. did well all summer on raw milk. On the other hand of those receiving the Pasteurized milk, 75 per cent. remained well, or nearly so, all summer, while 25 per cent. had one or more attacks of severe diarrhea. There were no deaths in either group of cases.

During the second summer a similar test was made with 45 infants. Twenty-four were put on raw modified milk; 13 of these had serious diarrhea, in 5 of whom it was so severe that they were put back upon heated milk; 10 took raw milk all summer without bad effects; 2 died, 1 from gross neglect on the part of the mother, the other from diarrhea. Of the 21 on Pasteurized milk, 5 had severe attacks of diarrhea, but all were kept on this milk except for short periods, when all food was omitted; 16 did well throughout the summer. One infant, markedly rachitic, died.

The outcome of these observations during the two summers are summarized in the following table:—

Kind of Milk.	Number of infants.	Remained well for entire summer.	Number having severe or moderate diarrhea.	Average number days off milk during summer.	Average weekly gain in weight.	Average number days diarrhea.	Deaths.
Pasteurized milk, 1,000 to 50,000 bacteria per c.c.	41	31	10	3	4 oz.	3.9	1
Raw milk, 1,200,000 to 20,000,000 bacteria per c.c.	51*	17	34	5.5	3.5 oz.	11.5	2

Although the number of cases was not large, the results, almost identical during the two summers, indicate that even a fairly pure milk when given raw, in hot weather, causes illness in a much larger percentage of cases than the same milk given after Pasteurization. A considerable percentage of infants, however, do apparently quite as well on raw as on Pasteurized milk.

Observations Upon the Use of Feeding Raw and Heated Milk in Older Children.—The children over three years of age who received unheated milk, containing at different times from 145,000 to 350,000,000 bacteria per c.c., showed almost no gastro-intestinal disturbance. The conditions at three institutions will serve as examples.

In the first of these an average grade of raw milk was used which, during the summer contained from 2,000,000 to 30,000,000 bacteria per c.c. This milk was stored in an ice-box until required. It was taken by the children unheated and yet no case of diarrhea of sufficient gravity to send for a physician occurred during the entire summer. This institution was an orphan asylum containing 650 children from three to fourteen years of age; viz., three to five years, 98; five to eight years, 162; eight to fourteen years, 390.

A second institution used an unheated but very pure milk which was obtained from its own farm. This milk averaged 50,000 bacteria per c.c. The inmates were 70 children of ages ranging from three to fourteen. In this institution not a single case of diarrheal disease of any importance occurred during the summer.

In a third institution an average grade of milk was used which was heated. This milk before heating contained 2,000,000 to 20,000,000 bacteria per c.c. The institution was an infant asylum in which there were 126 children between the ages of two and five years. There were no cases of diarrhea during the summer.

These clinical observations taken in connection with the bacteriological examination at the laboratory show that, although the milk may come from healthy cattle and clean farms, and be kept at a temperature not exceeding 60° F., a very great increase in the number of bacteria may occur. Furthermore, this may occur without the accumulation in the milk of sufficient poisonous products or living bacteria to cause appreciable injury in children over three years of age, even when such milk is consumed in considerable amount and for a period extending over several months. Milk kept at temperatures somewhat above 60° F. was not met with in our investigations, but the histories of epidemics of ptomain poisoning teach that such milk may be very poisonous. It is also to be remembered that milk abounding in bacteria on account of its being carelessly handled is also always liable to contain pathogenic organisms derived from human or animal sources.

Results with Very Impure Milk Heated vs. Those with Pure or Average Milk Heated.—During the summer of 1901, we were able to observe a number of babies fed on milk grossly contaminated by bacteria. In 1902, a systematic oversight of all stores selling milk was instituted by the Health Department, so that the very worst milk was not offered for sale that summer.

* Thirteen of the 51 infants on raw milk were transferred before the end of the trial to Pasteurized milk because of serious illness. If these infants had been left on raw milk, it is believed by the writers that the comparative results would have been even more unfavorable to raw milk.

TABLE SHOWING THE RESULTS OF FEEDING DURING JULY AND AUGUST, 1901, IN TENEMENT HOUSES, OF 112 BOTTLE-FED INFANTS UNDER ONE YEAR OF AGE, AND OF 47 BOTTLE-FED INFANTS BETWEEN ONE AND TWO YEARS OF AGE WITH MILK FROM DIFFERENT SOURCES, AND THE NUMBER OF BACTERIA PRESENT IN THE MILK.

Character of milk.	Infants under one year.					Infants over one year.

The observations upon the impure milk of 1901 are of sufficient importance to be given in detail, although already mentioned in this report in the observations upon infants of both summers which were fed on "store milk." A group of over 150 infants was so divided that 20 per cent. were allowed to remain on the cheapest store milk which they were taking at the time. To about the same number was given a pure bottled milk from Briarcliff Farms, sent to their homes free of charge by Mr. Walter W. Law. A third group was fed on the same quality of milk as the second, but sterilized and modified at the Good Samaritan Dispensary. A fourth group received milk from an ordinary dairy farm. This milk was sent to a store in cans and called for by the people. A few infants fed on breast and condensed milk were observed for control.

In estimating the significance of the observations recorded in the tables, one should bear in mind that not only do different infants possess different degrees of resistance to disease, but that, try as hard as the physicians could, it was impossible to divide the infants into groups which secured equal care, and were subjected to exactly the same conditions. It was necessary to have the different groups in somewhat different parts of the city. It thus happened that the infants on the cheap store milk received less home care than the average, and that those on the pure bottled milk lived in the coolest portion of the city. Certain results were, however, so striking that their interpretation is fairly clear. It is to be noted that the number of infants included in each group is small.

There is nothing in the observations to show that fairly fresh milk from healthy cows, living under good hygienic conditions and containing, on some days, when delivered, as many as 200,000 bacteria per c.c., had any bacteria or any products due to bacteria that remained deleterious after the milk was heated to near the boiling point.

On the other hand it is possible that certain varieties of bacteria may, under conditions that are unsanitary, find entrance to milk and survive moderate heat or may develop poisonous products resistant to heat in sufficient amount to be harmful, even when they have accumulated to less than 200,000 per c.c.

Turning now to the results of feeding with milk which has been heated and which before sterilization contained from 1,000,000 to 25,000,000 bacteria per c.c., averaging about 15,000,000, though obtained from healthy cows living under fairly decent conditions and kept moderately cool in transit, we find a distinct increase in the amount of diarrheal disease. Though it is probable that the excessive amount of diarrhea in this group of children was due to bacterial changes which were not neutralized by heat or to living bacteria which were not killed; yet it is only fair to consider that the difference was not very great and that the infants of this group were under surroundings not quite as good as those on the purer milk.

Finally, we come in this comparison to the infants who received the cheap store milk Pasteurized. This milk had frequently to be returned because it curdled when boiled, and contained, according to the weather, from 4,000,000 to 200,000,000 bacteria per c.c. In these infants the worst results were seen. This is shown not only by the death rate, but by the amount and the severity of the diarrheal diseases, and the general appearance of the children as noted by the physicians. Although the average number of bacteria in the milk received by this group is higher than that received by the previous group, the difference in results between this group and the previous one can hardly be explained by the difference in the number of bacteria. The varieties of bacteria met with in this milk were more numerous than in the better milk, but we were unable to prove that they were more dangerous. Probably the higher temperature at which the milk was kept in transit and the longer interval between milking and its

* This infant died from enteritis and toxemia.
† This infant died of pneumonia. There had been no severe intestinal disorder noted.
‡ One of the four had pertussis, the remaining three died from uncomplicated enteritis.

use allowed more toxic bacterial products to accumulate.

Observations Upon Milk Feeding in Institutions.—During the summer of 1901, observations were made by Dr. Long in nearly all the institutions for children situated in New York City. He found, with three exceptions, that no particular care was taken to secure a supply of pure milk. Samples taken from the supply of the other institutions showed that the milk averaged over 1,000,000 bacteria per c.c. when delivered, and at half of them it averaged over 10,000,000 per c.c. The cream frequently contained 60,000,000 bacteria per c.c. The milk at two places contained at times over 100,000,000. At several special hospitals for young children the milk and cream contained on different days from 26,000,000 to 157,000,000 bacteria per c.c. Formaldehyde was also occasionally found, especially in the cream. Samples of milk were taken weekly from most of the institutions and examined as to the number of bacteria and in some cases also as to the varieties present.

As a rule to the children who were over three years old the milk was given raw, while for those under two years it was heated (sterilized). For those between two and three years, it was sometimes heated, sometimes not. In only two institutions was it possible to trace any epidemic of diarrhea among the infants and older children, and in these, the particulars of which are given below, the results cannot be reasonably attributed to the milk.

The first epidemic of diarrhea occurred at the New York Infant Asylum during June and July, 1901. There were in the institution 86 infants; 30 of these were bottle-fed and 56 were on breast milk. Of the 30 bottle-fed infants, 22 suffered from diarrhea. Of the 56 breast-fed infants, only 7 were affected. The epidemic was mild in character, only 2 infants dying.

This epidemic, which occurred during and after a period of very hot weather, at first glance might be ascribed to the milk. The fact, however, that 7 cases occurred among the breast-fed infants, that the cases occurred from time to time, not simultaneously, and that the milk used had been previously heated, points rather to an infection communicated from the sick to the well than to one conveyed by the milk, unless it was true that the milk had been contaminated in the wards.

In another institution an epidemic of moderately severe diarrhea occurred during the winter, in which at first all the cases came from one ward, and then later from a second ward. In this epidemic, infection through the milk was not conceivable, since the bottle-fed infants in the wards where no illness occurred received milk from the general supply.

General Conclusions.—In addition to the statistical reports of their observations, the different physicians who watched the infants in their homes were asked to state their own conclusions regarding the general problem of infant-feeding in the tenements. These general impressions are most suggestive and cannot fail to be of interest to all who are working at this difficult problem.

It was practically the unanimous opinion that the most important factor in securing good results is intelligent care. This covers much: clean bottles and nipples; the willingness and ability to carry out directions as to methods of feeding, quantities, frequency, the stopping of milk at the first signs of serious diarrhea, etc.; proper care ot the milk itself while in the house, and methods of sterilizing; suitable clothing and cleanliness of the children, and as much fresh air as possible.

Most of the physicians stated that, leaving out the very worst store milk in summer, the results were much less affected by the character of the milk than they had anticipated, and distinctly less than by the sort of care the infants received.

The surroundings alone had much less influence on results than was anticipated. For not only were breast-fed infants found doing well under the most unfavorable surroundings, but those also who received only the bottle as a rule did well, provided they received intelligent care and good milk.

The depressing effects of great atmospheric heat, *i.e.*, a temperature in the neighboorhood of 90° F., or over, were very marked in all infants no matter what their food. Those who were ill were almost invariably made worse, and many who were previously well became ill. A bad method of feeding, or rather a feeding without any method, was responsible for many failures when the milk itself was of good quality. Common mistakes were, feeding an infant every time it cried; giving it a full bottle no matter what the age of the child, and letting it take as much as it would; preparing a large bottle of food at one time, and warming it over from time to time until the child had taken the whole of it, or allowing the milk to turn sour in the feeding bottle. Quantities proper for single feedings were almost invariably disregarded. Proper washing of feeding bottles was seldom seen in a tenement house. Such matters as these are closely connected with intelligent care, which has been already considered.

The importance of the matters just mentioned, raises the question of how much can be accomplished by the distribution of printed slips of directions. It was the observation of the physicians that comparatively little can be accomplished by these alone. Such printed circulars are often treated by the tenement-house mother very much as most of us treat the printed advertisements which are left at our doors—seldom read and soon thrown away. Mothers are often anxious and willing, but ignorant and stupid. Many cannot read and many more have not the wit to apply in practice what they read. When however, such printed advice was preceded or accompanied by personal explanation, it was found of great assistance. Personal contact is the only sure way to influence these people, and this must be frequently repeated to influence them permanently; as an aid to this, printed slips are useful. Printed direc-

tions, however, should be as simple as possible in statement, few in number, and touch only the most vital matters, telling the mother always what she is to do, not what she is not to do.

Summary.—The observations here recorded were made upon the groups of infants for periods of about three months only, and the conclusions drawn relate especially to the more immediate effects of the milk.

1. During cool weather neither the mortality nor the health of the infants observed in the investigation, was appreciably affected by the kind of milk or by the number of bacteria which it contained. The different grades of milk varied much less in the amount of bacterial contamination in winter than in summer, the store milk averaging only about 750,000 bacteria per c.c.

2. During hot weather when the resistance of the children was lowered, the kind of milk taken influenced both the amount of illness and the mortality; those who took condensed milk and cheap store milk did the worst, and those who received breast milk, pure bottled milk, and modified milk did the best. The effect of bacterial contamination was very marked when the milk was taken without previous heating; but, unless the contamination was very excessive, only slight when heating was employed shortly before feeding.

3. The number of bacteria which may accumulate before milk becomes noticeably harmful to the average infant in summer, differs with the nature of the bacteria present, the age of the milk, and the temperature at which it has been kept. When milk is taken raw, the fewer the bacteria present the better are the results. Of the usual varieties, over 1,000,000 bacteria per c.c. are certainly deleterious to the average infant. However, many infants take such milk without apparently harmful results. Heat above 170° F. (77° C.) not only destroys most of the bacteria present, but, apparently, some of their poisonous products. No harm from the bacteria previously existing in recently heated milk was noticed in these observations unless they had amounted to many millions, but in such numbers they were decidedly deleterious.

4. When milk of average quality was fed sterilized and raw, those infants who received milk previously heated did, on the average, much better in warm weather than those who received it raw. The difference was so quickly manifest and so marked that there could be no mistaking the meaning of the results. The bacterial content of the milk used in the test was somewhat less than in the average milk of the city.

5. No special varieties of bacteria were found in unheated milk which seemed to have any special importance in relation to the summer diarrheas of children. The number of varieties was very great, and the kinds of bacteria differed according to the locality from which the milk came. None of the 139 varieties selected as most distinct among those obtained, injured very young kittens when fed in pure cultures. A few cases of acute indigestion were seen immediately following the use of Pasteurized milk more than thirty-six hours old. Samples of such milk were found to contain more than 100,000,000 bacteria per c.c., mostly spore-bearing varieties. The deleterious effects, though striking, were not serious nor lasting. At the present time there is in New York City, no general sale from stores of "Pasteurized" or "sterilized" milk, so that it is here very rare for such milk to be used thirty-six hours after heating.

6. After the first twelve months of life, infants are less and less affected by the bacteria in milk derived from healthy cattle. According to these observations, when the milk had been kept cool the bacteria did not appear to injure the children over three years of age, at any season of the year, unless in very great excess.

7. Since a large part of the tenement population must purchase its milk from small dealers, at a low price, everything possible should be done by Health Boards to improve the character of the general milk supply of cities by enforcing proper legal restrictions regarding its transportation, delivery, and sale. Sufficient improvements in this respect are entirely feasible in every large city to secure to all a milk which will be wholesome after heating. The general practice of heating milk which has now become a custom among the tenement population of New York is undoubtedly a large factor in the lessened infant mortality during the hot months.

8. Of the methods of feeding now in vogue that by milk from central distributing stations unquestionably possesses the most advantages, in that it secures some constant oversight of the child, and since it furnishes the food in such a form that it leaves the mother least to do, it gives her the smallest opportunity of going wrong. This method of feeding is one which deserves to be much more extensively employed, and might, in the absence of private philanthropy, wisely be undertaken by municipalities and continued for the four months from May 15 to September 15.

9. The use, for infants, of milk delivered in sealed bottles, should be encouraged whenever this is possible, and its advantages duly explained. Only the purest milk should be taken raw, especially in summer.

10. Since what is needed most is intelligent care, all possible means should be employed to educate mothers and those caring for infants in proper methods of doing this. This, it is believed, can most effectively be done by the visits of properly qualified trained nurses or women physicians to the homes supplemented by the use of printed directions.

11. Bad surroundings, though contributing to bad results in feeding are not the chief factor. It is not, therefore, merely by better housing of the poor in large cities that we will see a great reduction in infant mortality.

12. The observations indicate that close percentage modification of milk, although desirable in difficult cases, is not necessary to obtain excellent results with the great majority of infants,

and that a certain adjustment of a healthy infant to its food is usually soon secured.

13. While it is true that even in the tenements the results with the best bottle-feeding are nearly as good as average breast-feeding, it is also true that most of the bottle-feeding is at present very badly done so that as a rule the immense superiority of breast-feeding obtains. This should, therefore, be encouraged by every means, and not discontinued without good and sufficient reasons. The time and money required for artificial feeding, if expended by the tenement mother to secure better food and more rest for herself, would often enable her to continue nursing with advantage to her child.

14. The injurious effects of table food to infants under a year old, and of fruits to all infants and young children in cities, in hot weather, should be much more generally appreciated.

THE DEGREE TO WHICH SUBSTANCES AGGLUTINATING THE DYSENTERY BACILLI ARE PRESENT IN THE BLOOD OF NON-INFECTED PERSONS.*

BY LAWRENCE B. PILSBURY, A.B., M.D.,

OF NEW YORK;

FROM THE DEPARTMENT OF BACTERIOLOGY OF THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THIS study was undertaken to determine (1) whether the different varieties of the dysentery bacillus of Shiga, would not react with serum from individuals suffering from various diseases (2) whether the acid and the non-acid types would not react differently with the same serum and (3) whether, if the bacilli reacted with the blood of adults the blood of infants also possessed the agglutinating substance. Recent observations tend to show that reaction of these bacilli to non-dysenteric serum does occasionally occur in fairly high dilutions, but the data so far obtained have been insufficient to determine the exact extent to which this reaction takes place. Several rather interesting questions rest on these observations. In the first place, can it be predicated that agglutination of dysentery bacilli of the various types, occurs only with diluted serum from patients suffering, or having recently suffered, from infection with one or more types of dysentery bacilli; and in the second place, if in some dilution it does so occur, within what limits can it be regarded as proof of such infection.

It has been held by various observers, including Shiga, Flexner, Kruse and others, that the agglutination of the dysentery bacilli which is caused by the serum of patients suffering from acute epidemic dysentery, and which resembles the Gruber-Widal reaction, is sufficiently distinctive to be pathognomonic of that disease. Shiga, Kruse, Flexner, Park and Dunham, Strong, and Vedder and Duval all succeeded in isolating from dysenteric stools bacilli which gave the specific reaction and which have been until recently regarded by the investigators themselves as practically identical in all respects. Vedder and Duval, after an exhaustive comparative study of all these bacilli, came to the following conclusion, as set forth in the *Journal of Experimental Medicine*, for February, 1902: "We are therefore forced to the conclusion that the cultural characteristics are essentially alike;" and "we have been unable to discover any real or constant differences between the varieties." This study included bacilli isolated by themselves in Philadelphia, New Haven and Lancaster.

Speaking of the various bacilli, Dr. Flexner says, in the *University of Pennsylvania Medical Bulletin*, August, 1901: "The serum reactions have been of greatest importance. They are, moreover, unmistakable in significance; they indicate close relationship between the bacilli from Japan, Manila, Porto Rico and Germany, and they further render probable the identity of the epidemic dysentery of this country with that of the East and Germany." Dr. Flexner's comparative study included cultures obtained from Shiga, Kruse, Strong, and from his own assistants and no essential differences were found. Such morphological variations as were observed were referred to the medium, the temperature, and the rapidity of division and growth. Kruse laid no stress on differences found. Shiga says in his article on dysentery in *Twentieth Century Medicine*: "I have shown that Flexner's and Kruse's bacilli were agglutinated by the serum of a dysenteric patient in Japan and that therefore this test is sufficient to establish their identity with my own *Bacillus dysenteriæ*."

Several extensive outbreaks of dysentery occurring in this country were studied by Drs. Park and Dunham (*N. Y. Univ. Bulletin of the Medical Sciences*, Oct., 1902), including cases occurring at Tuckahoe, Mount Vernon and Waverly, in New York, Lakewood, N. J., Seal Harbor, Me., and a few in New York City. The dysentery bacilli were obtained from a typical case in Seal Harbor, from a similar case in Tuckahoe and from a number in New York City. In many cases in which no cultures were attempted serum was obtained and all of those having typical dysentery symptoms and giving a positive serum reaction were regarded as probably due to one or more of the varieties of the Shiga bacillus. Nearly all of the Tuckahoe cases gave a positive reaction, either typical or fairly so, within one hour in a 1 to 10 dilution. Twelve out of the 22 cases examined gave a positive reaction in a 1 to 50 dilution within one hour. These tests were made from four to eight weeks after the abatement of symptoms. Three months later the reaction was much weaker. Four out of six cases examined at Mount Vernon gave a positive reaction within one hour in a 1 to 20 dilution. Of the Lakewood cases three were examined two months after convalescence was established. One gave prompt reaction in a 1 to 50 dilution, another gave a moderate reaction, and the third was negative. Of the cases at Seal Harbor one gave a positive re-

*Wm. T. Lusk Memorial Prize Essay, 1903.

action and another gave none. Of cases in New York 8 out of 18 gave a positive reaction in one hour in a 1 to 10 dilution. Three of these cases had simple diarrhea symptoms and failed to react.

The acid-producing type of the Shiga bacillus was obtained from a number of cases of dysentery at the Foundling and Babies' hospitals by Dr. Martha Wollstein and at the Nursery and Child's Hospital by Dr. Katherine R. Collins. The ages of the infants varied from a few months to several years. The blood serum gave a positive reaction in about one-half the cases with the Shiga from those obtained by Shiga in Japan and Flexner in New Haven. They also differ from the latter in producing indol in peptone solution."

In regard to agglutination, Shiga says "That the blood of dysenteric patients during convalescence is able to agglutinate the *Bacillus dysenteriæ* (so-called Widal reaction), I have proven by hundreds of observations. Some reactions are positive in 1 to 130 dilutions. Usually, however, the reaction is positive in 1 to 20 or 50 dilutions. Occasionally in mild dysentery the reaction is negative." . . . "The agglutination tests

bacillus (Flexner's acid-producing culture) in a 1 to 50 dilution.

In 13 cases of dysentery in adults in New York City Dr. Park obtained in 7 a positive serum reaction in a dilution above 1 to 20. Under "The Agglutination of the Shiga Bacillus by Sera from Cases in which no Suspicion of Shiga Bacillus Infection Exists," Drs. Park and Dunham say: "We have met with four sera from patients in whom no suspicion of infection with dysentery bacilli existed which agglutinated the Shiga bacillus in dilutions of 1 to 100. The bacilli from Seal Harbor and New York cases agree in agglutination properties with those sent us by Dr. Flexner, obtained from Manila and Baltimore, but differ conducted with the blood of persons sick with other diseases or healthy individuals were always negative, although such tests were tried (blood serum or blister exudate) in 12 healthy persons, 16 cases of typhoid fever, 3 of intestinal catarrh, 3 of beriberi." Shiga suggests that the agglutinating power of a serum may vary not only with the character of the epidemic, but also with the nationality of the patient. "Especially must it be mentioned that the maximum limit of the agglutination varies according to the technic employed and the individual judgment of the observer." In summing up he says further: "*Bacillus dysenteriæ* is agglutinated only by the blood of dysenteric patients; never by the blood of those

sick with other diseases or of healthy individuals."

In the *Deutsche medicinische Wochenschrift*, Oct., 1900, p. 637, Kruse says that many of the sera examined by him gave a reaction in dilutions of 1 to 100, 1 to 250, and one in a dilution of 1 to 1,000, while 25 specimens from well persons were either negative or gave a reaction only in dilutions of 1 to 10 or 1 to 20. Flexner found that with the Shiga, Kruse and Flexner bacilli "normal blood controls (1:10) were uniformly negative," but does not state how much time was allowed for reaction to occur. Lieut. Strong (Report Surg. Gen. of Army, 1900) tested his Manila bacillus with serum from 100 individuals. Of these 12 were well and the others were suffering from various disorders, as malaria, typhoid, rheumatism, tuberculosis, venereal diseases, paraplegia, abscess, acute mania, constipation, diarrhea, bronchitis, dengue, sprue, and 17 were surgical cases. Two gave a previous history of dysentery. In all these cases a 1 to 10 dilution was employed and observation made at the end of thirty minutes. The result showed a partial reaction in the case of one healthy individual and a positive reaction in one surgical case. The rest were all negative. Dr. Strong says: "The dilutions of blood serum used may be considered rather low for the time limit, but these 100 reactions seem to show that the agglutination does not occur with ordinary blood serum in these dilutions." He does not show by his table whether the two cases which did react were those which had previously suffered from dysentery. Dr. Strong in a letter to Dr. Flexner says, "The agglutination reaction is not invariable."

In the *Bulletin of the Johns Hopkins Hospital* for 1900, XI, p. 231, Dr. Flexner says, speaking of the agglutination test: "While the absolute value of this test in determining the specificity of bacteria may be open to doubt, its use in differentiation is now unquestioned." By this test a bacillus was separated (in Manila) of which he says on page 39: "Agglutination was constant and sensitive with blood-serum of host as well as the sera of other individuals suffering from dysentery. Inactive with normal serum and serum from cases of typhoid fever, malaria, and beriberi."

Vedder and Duval obtained positive agglutination reactions with dysenteric sera in one hour and in dilutions varying from 1:30 to 1:500. Loose skein clumping was observed by them and also by Kruse and Flexner. Shiga's antidysenteric serum clumped the Shiga bacillus in dilutions of 1 to 300 and 1 to 500, but failed to clump the acid-producing (Flexner) type in the same dilutions. Vedder and Duval remark that: "While the agglutinating properties of the bacilli from different sources are very much the same still there are differences in degree." (This I found to be true in my own observations of the Shiga and acid [Flexner] bacilli.) "Normal blood was frequently used as a control for the specific sera. We never obtained an agglutination in any of these control tests, no matter what dilution was used."

The Bacilli.—The bacilli employed were from Shiga's Japan (alkali type) and Flexner's Manila (acid type) cultures. They answered in all respects to the descriptions of the various observers, being slender rods with rounded ends, about 1 to 3 microns in length, appearing singly, sometimes also in pairs, but having no tendency to form groups. On agar and glucose agar involution forms rapidly developed and the bacilli also showed striking increase in length when multiplying in broth. They grew well both at room temperature and in the incubator. On agar and glucose agar the streak gave a growth of uniform width, at first whitish gray and translucent and later becoming yellowish or creamy and opaque, with crenated edges. Broth was uniformly clouded with sedimentation and no pellicle was formed. No differences in growth between the two were to be found in the ordinary media. The bacilli had very active Brownian movement, but no appreciable motility.

The clumping which occurred varied greatly in degree and was recorded under four heads. Skein clumping was frequently observed as a loose but fairly typical arrangement in which the bacilli were unusually long, were joined end to end and still adhered closely, leaving few or no free bacilli in the field. The term "complete" was applied only to those cases in which there were no free bacilli and in which practically all of the clumps were large. These were sometimes of the skein variety and sometimes much more compact. It is only fair to say that cases which showed as typical a reaction as this were comparatively few. The term "good" was applied to those cases in which there were found large and small clumps and a few free bacilli in the field. These cases were numerous, especially in dilutions of 1 to 10 and 1 to 20. Under the head of "fair" were classified those cases which showed fairly good sized clumps, but a great many free bacilli being found and retaining their Brownian movement to a considerable degree. Those cases were classified as "slight" which showed any uniform grouping, however little, well scattered over the field. In the negative cases there was no uniform attempt at grouping, although in some cases a few bacilli here and there would be found clinging together. The rest were all discrete and showing very active molecular movement.

By this classification an attempt has been made not only to signify the presence of a reaction, but to indicate as nearly as may be the degree of completeness of the clumping which occurred. It is believed that this multiplication of terms will tend to clearness rather than confusion and will contribute somewhat to the scientific exactness of the results. It seems scarcely sufficient to say simply that a reaction has or has not occurred when all degrees of clumping are possible and do occur. It must be remembered that the personal equation enters largely into observations of this sort and perhaps more extended classification may

help to reduce this to a minimum. No doubt many discrepancies in observation are due to individual differences in interpretation of what is seen. It is clearly impossible to create an absolute and arbitrary standard in agglutination work and the most that can be hoped for is a classification which will make the different degrees of clumping intelligible and fairly exact. It is possible that some cases which have been recorded by various observers as negative may have shown slight clumping which was passed over because it could not be considered a typical reaction. It is also quite possible that many of the cases recorded in this paper as showing slight clumping might be regarded by others as entirely negative. It is hoped that the classification employed will make clear what was actually found.

Technique.—These observations were made at the suggestion and under the direction of Prof. W. H. Park, in the Carnegie Laboratory of the New York University and Bellevue Hospital Medical College. The blood specimens were obtained at Bellevue Hospital and in the College Clinic. Inoculation was made upon agar from a stock culture and each day fresh streak cultures were made upon agar or glucose agar slants. These tubes remained in the incubator over night. Each day broth cultures were made from the twenty-four hour growth on agar and these were allowed to remain at room temperature over night for use on the following day. The ordinary hanging-drop preparation was employed and all dilutions were made with plain sterilized water. In all cases a hanging-drop of the plain broth culture was used as a control and this control drop failed to show the slightest clumping with either bacillus in any instance, the appearance corresponding exactly with that observed in specimens recorded as negative. The blood was gathered in capillary tubes and time allowed for the separation of clot and serum to take place. In some cases where this did not occur very thoroughly the drop contained many corpuscles and showed distinct color in low dilutions. It is not believed that this had any material influence upon the results obtained. Shiga used whole blood in many of his tests and places the agglutinating power of the blood at one-half that of the serum alone.

Even in those few cases in which evaporation had taken place through imperfect sealing of the tube, there was no marked difference in the results obtained, although the dilution was necessarily approximate. Observations were made at periods varying from one to eight hours, in the great majority of cases being made at the end of three hours. In the accompanying table "C" stands for complete, "G" for good, "F" for fair, "S" for slight, and "N" for negative.

Results.—The difference between the agglutinating capability of the Shiga and Flexner cultures was quite noticeable. In most instances among the specimens of blood examined the acid type bacillus dropped out first and in a very few instances only did it exceed the alkali bacillus in agglutinating capability. It occasionally happened that the results were perfectly parallel, but these instances were comparatively rare except where no reaction occurred, as with the blood of infants. It is interesting to note that in the only two typhoid specimens which were obtained the Flexner culture gave good clumping in all the various dilutions, while the Shiga culture in one gave a good reaction in only a 1 to 10 dilution and in the other in 1 to 10 and 1 to 50 dilutions. That the clumping in the 1 to 50 dilution exceeded that in the 1 to 20 in this specimen may have been purely accidental, although it occasionally occurred that clumping was better in a 1 to 20 than in a 1 to 10 dilution.

In three cases of appendicitis which were examined the results show a more decided tendency to clump than in most cases not associated with any intestinal lesion. In one the Shiga culture gave good clumping in three hours in dilutions of 1 to 10 and 1 to 50, complete clumping in 1 to 20 and fair clumping in 1 to 100, while the Flexner culture gave good clumping in a dilution of 1 to 10, complete clumping in 1 to 20, fair clumping in 1 to 50 and slight clumping in 1 to 100. In no other instances was complete clumping found in a 1 to 20 dilution. It would be interesting to pursue the investigation farther in regard to appendicitis and typhoid cases. One case of alcoholic enteritis examined gave a marked reaction in a low dilution and some clumping all the way through. The cases of tuberculosis examined showed nothing very noteworthy except that two gave complete clumping with the Shiga bacillus in a 1 to 10 dilution. The cases of pneumonia gave no striking results, but two or three of them were convalescent.

To sum up, those cases which gave complete clumping with the Shiga culture in a 1 to 10 dilution were two of tuberculosis, one of malaria, one of alcoholic enteritis, one of acute pleurisy, one of pernicious anemia, and one surgical case. The only instances in which the Flexner culture gave complete clumping was in a case of pernicious anemia, in a 1 to 10 dilution and in a case of appendicitis in a 1 to 20 dilution. No complete clumping occurred with either culture in a higher dilution than this. The Shiga alkali culture was never negative in all dilutions except in the cases of infants under one year. The Flexner acid culture was negative throughout in the infantile cases, in three children of seven, four and two years, respectively, and in one adult. All patients were adults except those whose age is given in the table.

It was found in all cases of infants under one year that there was a complete absence of reaction, except in one case of a ten months' old child where very slight clumping occurred in a 1 to 10 dilution. While the number of cases examined was not sufficiently large to be conclusive, it seems probable that the agglutinating power in non-dysenteric serum is absent in children under one year. That it may be present in cases of dysentery in a 1 to 50 dilution or over is shown by the cases in

the Foundling and Nursery and Child's hospitals, many of whom were under one year. However, some of the cases in the Foundling and Nursery and Child's hospitals failed to give any reaction. Nearly all the children examined by me who were under five years gave proportionately less clumping than did children above that age. The serum from very few of the children between one year and five years gave any clumping above a 1 to 20 dilution and in only one of them was there good clumping in that dilution. Of all the persons examined there was only one in which there was any clumping whatever in a 1 to 100 dilution. It would seem, then, that the agglutinating power of the serum has some relation to the age of the individual, but this difference is less noticeable above the age of five years and depends greatly upon the intestinal condition. The adults examined included individuals of all ages and various nationalities.

Conclusions.—It is realized that these investigations are only tentative, but they seem to warrant certain conclusions:

1. That the serum of non-dysenteric adult patients does agglutinate the Shiga and acid type (Flexner) bacilli frequently in a 1 to 20 dilution and occasinally in a dilution as high as 1 to 100.

2. That this agglutinating power is wanting in the blood of non-dysenteric young infants (under one year) rarely being present even in a 1 to 10 dilution.

3. That there are certain differences in agglutinating capability between the Shiga and acid type (Flexner) bacilli, the former in these tests clumping somewhat more readily than the latter.

4. That a decided and prompt reaction, under two hours, with the *Bacillus dysenteriæ* in dilutions of 1 to 20 or higher in young subjects (under one year) and in 1 to 50 or higher in older persons who have not recently suffered from chronic or subacute intestinal disease, is probably pathognomonic of acute epidemic dysentery.

GENERAL CONVULSIVE TIC WITH COPROLALIA.

BY HARRY MORELL, M.D.,
OF LITCHFIELD, MINNESOTA.

CONVULSIVE tic or Gilles de la Tourette's disease is a rare motor neurosis characterized by violent involuntary twitchings. The movements, as a rule, affect the face, but in severe cases all the muscles of the body may be involved. Associated with the muscular movements, are explosive utterances which consist of inarticulate cries, sometimes resembling the bark of a dog; these cries or utterances are made suddenly and automatically and accompanied by grimaces and contortions of the facial muscles. At times the patient will shout at the top of his voice obscene or profane words. To this condition coprolalia has been applied. A word heard may be mimicked and parrot-like be repeated over and over again; this is termed echolalia, echokinesis when actions are imitated.

The patient with the fully developed disease suffers a great deal from the spasms, but, generally, retains his intelligence, although it may be impaired when the disease is of long standing. By energetic will power the patient may repress the twitchings for a time, but they return sooner or later with increased frequency and vigor, the same with the coprolalia, if the patient is alone and unobserved and away from noise and excitement, the barking may cease, as it did with the lad whose history is attached. This patient was isolated and did not make any outcry for two or three months, until a fire occurred in the vicinity where he was confined, when the barking and spasms returned and did not abate for a week. The cessation of the tic during work or being occupied with something where the mind is employed, is not only due to self-control, but also to the diversion of the attention.

Author's case of convulsive tic during spasmodic contraction, involving the depressor anguli oris and levator menti muscles.

This distressing affection has been taken for chorea.* "Tis has no more in common with chorea, be it acute or chronic, than it has with epilepsy; indeed, I am inclined to the opinion it has much less. Furthermore, it has absolutely nothing in common with acute, humoral, Sydenham's chorea, nor with degenerative, parenchymatous, Huntington's chorea, and that the term chorea should never be thought of in connection with this disease, and, finally, that tic being in a majority of instances a degenerative neurosis, it conforms in concurrence, in development, in progression, in obstinacy and unresponsiveness to treatment with other degenerative diseases."

Fully developed cases do not offer any difficulty of diagnosis. As long as the tic is confined to the facial muscles it may be confused with localized muscular spasms, but if it extends to the neck muscles the diagnosis is made probable; it is confirmed when coordinated ties are observed. In simple motor tic or tic douloureux convulsive twitching of the facial muscles is observed on the affected side. This is a reflex condition caused by

*Joseph Collins, MEDICAL NEWS, Dec. 11, 1897

irritation of some of the branches of the fif nerve. Habit tic or facial spasm should not confounded with general tic; in these the spas are generally unilateral. In organic disease the cortex, as cortical epilepsy, the spasms a observed to start in the facial muscles but soo extend to the arms and finally over the enti side.

The majority of the cases of this deplorab condition are chronic and progressive in characte Oppenheim has seen cases recover completel Charcot has observed long remissions in son cases. As a rule one would be inclined to giv rather a dubious prognosis as to a complete cure

The following is a short history of one of thes cases associated with coprolalia:

Case.—L. I., a young man eighteen years o age. His father is living and healthy. Hi mother died at the age of forty-three. Cause not known, but it was not a nervous affection. He has five brothers living; all are strong and healthy with the exception of one who is extremely nervous. The patient is robust and of splendid muscular development and, as far as he is aware, was never sick in his life. His father tells me that there were no unusual complications attending the patient's birth, nor convulsions in infancy. There are no anatomical stigmata present. When twelve years old he noticed that the muscles of his face would twitch. This twitching would come on very suddenly and involuntarily. The spasms gradually became more violent and extended to the muscles of the neck, to the shoulders and down to both arms, which twitch violently and simultaneously. Two years later, the lightning-like contractions of the muscles of the face were accompanied by a noise which resembled "hum" and "whea;" these were alternated with a peculiar cry or bark at the top of his voice. Try as he might he could not control them. The patient has been in this condition for the past six years. If any unusual excitement occurs the barking is almost continuous. He says he is a nuisance to himself and everyone who comes within the range of his voice. It matters not where he is—on the street, in a shop or in a theater—he barks incessantly and at other times uses nasty language. He is an attraction wherever he is on account of his peculiar bark or cry and the distressing, uncontrollable facial contortions with the loud spasmodic sniffing.

In regard to the treatment. This patient has been given almost every drug recommended for this condition; in addition various therapeutic measures have been used, as baths, electricity, massage, etc. He has gone the rounds of the hospitals, and various practitioners have treated him, and the result has not been encouraging. When he presented himself to me, I placed him in isolation and gave nitrate of silver in increasing doses. After having been on this treatment for about three weeks the coprolalia had entirely left him and the tic was diminished somewhat. After two months of isolation the barking did not return until a fire occurred in the vicinity of the hos-

tal, when the coprolalia and loud noises re- ned, which lasted a week or so. The patient s in isolation for eight months. During that e he seemed to improve, but after that, when started to go out occasionally, the symptoms adually returned. Since his return to "public e" the disease seems uninfluenced by the treatent given.

The illustration shows plainly the convulsive pasm of the muscles of the face.

HE TREATMENT OF ANTERIOR DISLOCATION OF THE SHOULDER, WITH REPORT OF A CASE IN WHICH REDUCTION WAS PREVENTED BY THE DETACHED GREATER TUBEROSITY.*

BY GEORGE TULLY VAUGHAN, M.D.,

OF WASHINGTON, D. C.:

ASSISTANT SURGEON-GENERAL, U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE; PROFESSOR OF SURGERY OF GEORGETOWN UNIVERSITY, WASHINGTON, D. C.

Dislocation of the shoulder is such a common injury and its treatment so important in order to prevent serious disability that no apology is needed for inviting your attention to what might seem a trite and uninteresting subject. It is variously estimated that from 40 to 65 per cent. of all dislocations are of the shoulder, and of these the large majority—according to Flower, 75 per cent.—belong to the subcoracoid variety. The other two varieties of anterior dislocation, the intracoracoid and subclavicular are very infrequent. In attempting reduction the following methods should be used and in the order given.

1. *Direct Reposition.*—This is one of the oldest methods in use. The surgeon places his fingers beneath and to the inner side of the head of the humerus with thumbs on the acromion process and attempts to press or pull the head of the bone into place. Anesthesia may or may not be necessary. It often succeeds in recent cases with slight muscular contraction and with the head of the bone very slightly displaced.

2. *Extension and Counterextension.*—This is also one of the oldest methods, but one which I believe is not appreciated at its full value. My attention was especially attracted to this method by reading an article by Stimson about two years ago in which he reported ten cases successfully treated, and in no case was it necessary to continue the extension longer than six minutes. Stimson advised the use of a canvas cot with a hole cut in it large enough to let the arm come through. The patient reclines on the cot with his arm projecting through the hole and a weight of about ten pounds attached to the wrist. The method was applied as follows in my cases:

With the patient in the dorsal position, place a folded sheet in the axilla of the dislocated arm and let the ends extend diagonally across, above and below, the opposite shoulder where they are held by an assistant. The surgeon flexes the

* Read at the meeting of the Association of Military Surgeons of the United States, at Boston, May 19, 20, 21, 1903.

forearm on the arm, to relax the biceps, takes hold of the arm with both of his hands just above the elbow and makes gentle, steady traction, at first in the line of the displacement, but as the traction increases, the arm is carried away from the side to an angle of about 45 degrees. The traction is continued, not too strongly, but just enough to make the muscles tense. An assistant should be ready to relieve the surgeon when he becomes tired, as he is apt to do in two or three minutes, and the change should be made without relaxing traction on the arm. In a short time, from one to six minutes, you gain the confidence of the muscles by the gentle steady traction, the spasmodic contraction ceases, the muscles relax and the head of the bone slips into place.

While this method is one of the oldest in use for the reduction of dislocations of the shoulder, there are certain features which, if not new, do not seem to be fully appreciated; namely, the importance of using *gentleness* with *persistence* and no great degree of force, and of keeping up the traction several minutes or until the muscles are tired out.

It is doubtful if this method is of much value in old cases. I have tried it in only two old cases, one a subclavian dislocation of eighteen days' standing, in which a number of attempts at reduction had been made both by laymen and physicians. I tried the traction method for ten minutes while the patient was under the influence of ether, without success, and reduction was finally effected by Kocher's method of manipulation. The other will be reported in the latter part of this paper.

This plan especially appeals to me and seems worthy of trial because: (*a*) It is free from pain; (*b*) it does not require anesthesia; (*c*) it is perfectly safe in recent cases; (*d*) it can be used by the general practitioner who may hesitate to attempt more complicated methods; (*e*) it does not lacerate or injure the tissues and thus interfere with the success of other methods which may be attempted; (*f*) it succeeds in the large majority of cases. During the last two years my assistants and myself at the Emergency and Georgetown University Hospitals have used this method in about 15 cases of recent dislocation with only two failures.

3. *Kocher's Method.*—This is probably the best method of manipulation and should be tried if *direct reposition* and *extension* and *counterextension* fail, but it is painful—usually requiring anesthesia, and in unskilled hands may result in considerable injury to the tissues. It consists of three steps: (*a*) Flex the forearm of the affected side to a right angle with the arm, press the elbow to the side, and rotate the humerus outward by carrying the forearm around until it stands directly out from the side. Unless the humerus rotates outward without difficulty, this method will fail. In some cases it may be made to rotate by making traction in the long axis of the arm. (*b*) Still holding the forearm at right angles to the body, bring the elbow forward or forward and slightly inward until the arm is horizontal. If the head of the bone does not slip into place during the second step, make (*c*) internal rotation by placing the hand on the opposite shoulder and lowering the elbow into position.

4. *Arthrotomy.*—If all three methods given fail in spite of anesthesia, the dislocation should be reduced by arthrotomy, provided the circumstances permit the performance of an aseptic operation. The methods by using the foot, knee, or fist in the axilla are not to be recommended on account of the danger to the axillary vessels, to the circumflex and posterior thoracic nerves, and even to the bones themselves—the humerus or ribs. I have in two cases fractured the ribs of patients with a moderate degree of force—using the fist as a fulcrum in the axilla.

The following case shows the impossibility of reducing some cases of dislocation without arthrotomy:

Case.—J. R., white, male; aged sixty years; farmer; native of Virginia, fell down a flight of stairs January 20, 1903, striking his left shoulder against the doorpost and causing a subcoracoid dislocation. A physician was called and attempted reduction with the foot against the side, by binding the arm to the side over a ball in the axilla, using anesthesia but without success. March 21, two months after the injury, he applied for relief, as he knew there was something wrong with the shoulder. The deltoid was wasted, the acromion prominent, the shoulder joint stiff and the patient suffered considerably from pain in the arm and hand. The head of the bone could be felt beneath the coracoid process. Under ether all methods were tried without success—direct reposition—extension and counterextension, Kocher's method, circumreduction, extension upward, and even with the foot in the axilla. The head of the humerus rotated outward in Kocher's manipulations but reduction could not be effected. An incision was made over the glenoid cavity from the anterior portion of the acromion process down the shaft of the humerus. Bony material was found occupying the glenoid cavity and was at first thought to be new bone but after dissecting it out and examining the humerus, it was recognied as the detached greater tuberosity. Adhesions existed around the margin of the fragment and the glenoid cavity beneath was found smooth and unchanged. Reduction was then easily effected by pressure in the axilla with adduction of the arm.

The wound was closed without drainage; recovery was uneventful and the patient was discharged March 30, nine days after operation. The patient expressed great relief from removal of pressure on the nerves in the axilla.

A Peculiar Action of the Roentgen Rays.—After having subjected a number of rabbits and guinea-pigs to the influence of the Roentgen rays for a number of hours on successive days, A. Schönberg (Münch. med. Woch., Oct. 27, 1903) was astonished to find that all the animals had become sterile. The general health and sexual vigor were normal, but spermatozoa were absent.

THE MORTALITY OF DIPHTHERIA IN PRIVATE PRACTICE UNDER THE ANTITOXIN TREATMENT.

BY JOHN ZAHORSKY, M.D.,
OF ST. LOUIS, MO.

It is generally understood that the ordinary practitioner depends on his own results more than general statistics in estimating the value of a remedy. The published reports of the death-rate of diphtheria under the antitoxin treatment, while giving the opponents of the serum treatment a good field for controversial athletics, really are the least important in convincing the average practitioner. The physician conscientiously tries the antitoxin in a series of cases, his results are so much better than on any other treatment, and henceforth a little debate on the relative value of certain statistics gathered from hospitals and foundling asylums, makes no impression on his convictions.

Some months ago, in studying the mortality statistics given by recent authorities, I felt convinced that the figures are far in excess of the death-rate of diphtheria in private practice. Thus, for several years I have not had a single death, and in speaking to other physicians I was informed also that their death-rate was almost nothing.

I resolved, therefore to collect a few statistics among the physicians of St. Louis. I wrote to about one dozen physicians, who, I knew, had large practices among children, and who, I was sure, were ardent advocates of the antitoxin treatment, and used it promptly in every case. I was also assured that these gentlemen took pains to get a good serum and used it in sufficient doses. The answers really surprised me.

As the first two years of the antitoxin treatment was really in the experimental stage, the inquiry related to the last five years (1898-1902). But before giving these figures, it might be profitable to notice briefly some of the statistics on this subject.

	Per cent.
American Pediatric Society's Collective Investigation, mortality	13.7
Siegert (Jahrb. f. Kinderh., 1900), mortality	16.4
Spolverini (Il Policlinico, 1900), mortality	16.
Report of Health Department, Chicago, 1901, mortality	6.8
Report of Mass. State Board of Health, 1900, mortality	10.4

Various reports from Health Officers in England and Germany give the average mortality as about 15 per cent. Of course this includes all cases, in hospitals, asylums, moribund cases, and cases in infants of low vitality.

The collective investigation of the American Pediatric Society was made while the use of the serum was still in the experimental stage.

In the following table I give the number of cases treated by the physicians, who kindly responded to my inquiry. It should be understood that these patients were treated by the physicians from the beginning, and do not include moribund cases seen in consultation.

	No. Cases.	Deaths.
Dr. B. Bribach	150	1
Dr. H. A. Auler	627	7
Dr. E. W. Saunders	220	0
Dr. L. H. Behrens	20	0
Dr. M. J. Hopkins	38	0
Dr. E. W. Eberlein	61	5
Dr. W. S. Barker	250	7
Dr. G. M. Tuttle	60	3
Dr. J. C. Falk	80	1
Dr. W. L. Johnson	17	0
Dr. M. J. Lippe	32	0
Dr. John Zahorsky	55	0
Total	1,610	24

Mortality, 1.5 per cent.

Instead of 10 or 15 per cent., the death-rate in private practice should be not over two per cent. This includes laryngeal cases, many of which were intubated.

Dr. Bribach's only death was in a young infant with laryngeal diphtheria, the tube had been expelled and the infant was considered almost well, but the parents failed to notify the doctor when the stenosis appeared again.

Dr. Auler reports that several of his cases were practically moribund, and really should not be counted in. Out of 27 laryngeal cases treated with antitoxin and intubation, he lost only two.

Dr. L. E. Newman writes that in an extensive family practice, he has not had a single death since he uses antitoxin.

Dr. E. M. Senseney was among the first to use the serum in this city, and has had no death from this disease since.

Dr. E. W. Saunders feels that no patient suffering with diphtheria should die. A death means an error in technic, and not in the inefficiency of the serum treatment. In every suspected case he at once injects antitoxin and gives pilocarpine internally. He insists on a reliable serum, and the initial dose should be large enough to certainly neutralize all toxin in the blood and all that may be formed in the next few days.

From this correspondence I gather that, while these physicians have full confidence in the antitoxin curing diphtheria in a child who has an average constitutional resistance to disease, they admit that certain errors may be made, which may here and there cost a life.

The following are some of the common mistakes which may end disastrously:

(1) A diagnosis of simple tonsillitis is made and the patient is not seen for several days, when a severe case of diphtheria is found; (2) an insufficient dose of antitoxin is injected; (3) a worthless serum is injected, one either too old or prepared by an unreliable manufacturer; (4) a diagnosis of simple laryngitis is made in a primary laryngeal diphtheria.

Dr. Bribach makes it a rule to inject antitoxin at once in every case in which he cannot with certainty exclude diphtheria. He has had only one

death in five years and this he attributes to the carelessness of the parents.

While these reports are so gratifying, many deaths from diphtheria occur in St. Louis. I have been consulted in three moribund cases treated by physicians who had not made the diagnosis, or, at least, did not use the serum. Another case was given up by the attending physician (who did not believe in antitoxin), but was still saved by intubation and antitoxin.

Dr. Lippe related to me that he saw one child dead and the other dying in a family where a quack was in attendance.

I do not believe these statistics are singular, for I believe they can be duplicated anywhere, where physicians believe in the efficacy of diphtheria antitoxin and know how to use it.

MEDICAL PROGRESS.

MEDICINE.

A New Test for Bile in the Urine.—Since the usual bile-tests have proven very unreliable in the hands of A. Jolles (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 1 and 2), the following one is recommended: Ten cubic centimeters of urine are mixed in a test-tube with 2 to 3 c.cm. of chloroform and 1 c.cm. of a 10-per-cent. solution of borium chloride. The mixture is then centrifuged, the fluid above the chloroform and precipitate poured off, and the tube filled with distilled water, shaken and centrifuged a second time. In case of dark-colored urines this is repeated a third time. After the water is decanted, the chloroform and precipitate are shaken with five cubic centimeters of alcohol and then two or three drops added of an iodine solution, which is prepared as follows: 0.63 gm. of iodine and 0.75 gm. of corrosive sublimate are each dissolved separately in 125 c.cm. of alcohol, poured together, and then 250 c.cm. of pure hydrochloric acid added. In the presence of even faint traces of bile, a distinct green color is obtained. The reaction can be hastened by placing the test tube into hot water for a few minutes. Indican or hemoglobin do not interfere with the reaction. The presence of one-tenth milligram of bilirubin in 100 c.cm. of urine still gives a positive reaction.

Influence of Water on Nephritis.—In acute and chronic nephritis, L. Mohr and C. Dapper (Zeitsch. f. klin. Med., Vol. 50, Nos. 5 and 6) have found that a moderate restriction of water (up to 3 pints daily) will often influence the body favorably, so that the more energetic withdrawal of fluids will have a more pronounced effect upon the edema later on. The same observation may be made in cardiac cases. The elimination of nitrogenous principles and of phosphoric acid is not interfered with by this procedure unless the water is reduced to 40 ounces or less. Where it is imperative to give such small amounts, the system should be washed out occasionally by more liberal quantities. The amount of albumin in interstitial nephritis usually increases somewhat with deficient fluid, but this is of no account, being only a temporary phenomenon.

Intestinal Syphilis.—A rare case of primary intestinal syphilis of almost certain diagnosis came under the observation of C. Gutmann (Zeitsch. f. klin. Med., Vol. 50, Nos. 5 and 6). An infection was denied and there were no other signs of lues, so that the patient was considered tuberculous. At autopsy, however, the ulcers lacked all the characteristics of tuberculous lesions. They were seated in pairs or larger groups throughout the small intestine, but involved the lower portion of the jejunum more than any other part. There was a marked tendency to spread around the entire circumference of the gut in the form of a ring, with subsequent cicatrization and stenosis. The infiltration was marked and tumor-like, and the base smooth. Microscopically the lesions did not impose as a primary ulceration, but as a cell-infiltration, beginning in the upper layers of the submucosa and followed by necrosis extending into the inner muscular layer. What made the diagnosis almost certain was the presence of endarteritis in the smaller mesenteric vessels. During life the most marked symptoms were uncontrollable, diarrhea, intermittent temperature and rapidly advancing cachexia.

A New Reaction for Sugar.—In some urines which imperfectly reduce Fehling's and Nylander's solutions, and do not ferment or turn the plane of polarized light, it is possible to demonstrate the presence of pentose by means of orcin and hydrochloric acid. M. Bial (Zeitsch. f. klin. Med., Vol. 50, Nos. 5 and 6) finds that glucose and other sugars with six atoms of carbon will also give this reaction if a few drops of sesquichloride of iron solution are added before boiling. If the bluish green precipitate is dissolved in amyl alcohol and then examined with the spectroscope, the bands will, however, be different. This discovery may be of value in distinguishing between glucose and glucosamin, which, both form the same osazone when treated with phenylhydrazine.

Symptoms of Open Ductus Botalli.—The most usual cause of persisting communication between aorta and pulmonary artery is premature birth. Owing to general weakness and insufficient respiratory movements, the sudden change in respiration which is necessary to obliterate the duct, does not take place. There is frequently also a history of some constitutional disease on part of the parents, such as alcoholism. The symptoms often amount to no more than a moderate cyanosis and the prognosis is generally fair. According to A. Bittorf (Münch. med. Woch., Oct. 13, 1903), dulness to the left of the sternum, at the level of the second or third rib, due to dilatation of the pulmonic artery, is almost pathognomonic. Over this area there is often a systolic pulsation with a blowing systolic murmur, and an accentuated second sound. The murmur may also be heard over the apex and is not transmitted into the carotids and the pulse need not show any abnormalities. Frequently there is also an open foramen, but it is generally impossible to diagnose this during life. The Roentgen rays generally establish the diagnosis beyond doubt.

A Fatal Case of Poisoning by Quinine.—The literature of quinine poisoning being very scanty and a fatal case almost unique, the following instance should prove of interest. It is reported by R. H. Quill (Jour. Royal Army Med. Corps, Oct., 1903). The patient swallowed, evidently with suicidal intent, a quantity of sulphate of quinine in solution, amounting to about 240 grains. Within two minutes the symptoms of poisoning came on, beginning with retching and vomiting, which was favored by the prompt administration of an emetic. This was soon followed by almost total unconsciousness, slow and labored respiration, and a barely perceptible pulse, which, under very active stimulation, would return for a time only. A few hours later convulsions affecting mainly the lower extremities came on, and this was soon followed by death. Post-mortem examination showed the blood fluid and very dark in color. The brain was congested and the lateral ventricles were full of serum. The liver, lungs and kidneys were also congested, but otherwise healthy. There was no inflammatory or corrosive appearance of the

mucous membrane. The author believes that if the stomach pump had been efficiently used within a short time after the accident, it is very possible that the fatal issue might have been avoided.

Cordite Eaters.—A recent communication on this subject is published by J. W. Jennings (Jour. Royal Army Med. Corps, Oct., 1903), relating to his experiences in the South African campaign. He observed personally a number of cases where the men ate one or more strands of the cordite, which they took from their cartridges. These strands measure about 1¼ inches in length and $^1/_{25}$ of an inch in thickness. The symptoms are similar to those produced by amyl nitrite, the headache being extremely violent. When taken with beer or tea, cordite produces heavy sleep, followed by stupor lasting from five to ten hours. It is difficult to awaken the patient from this deep sleep and the dulness continues for some time. When taken in solution an immediate exhilarating effect results, inciting almost to demoniacal actions. This lasts for several hours, and is then followed by a deep sleep. The author does not believe that the habit is at all universal in the army, and the symptoms and effects are sufficiently forcible and unpleasant to prevent any but the most depraved resorting to either as a cerebral stimulant or sedative.

The Association of Heart Disease with Tabes.—There are many who do not regard endocardial lesions as of great importance or as a complicating factor when associated with tabes. B. F. Stahl (Am. Med., Nov. 14, 1903) believes that more emphasis should be laid on this condition and that it should command more consideration as regards treatment. Among 24 cases examined at one time, in the Philadelphia Hospital, cardiac lesions were present in 19, and the radial artery was appreciably affected in all but three cases. Only two of the patients had normal heart sounds in all the areas, 10 had accentuation, weakening or blurring of the sounds, and 12 presented clinical evidence of valvular disease. In 19 cases, syphilis was admitted or probable. The author believes that the intimate relationship existing between syphilis and tabes and the pronounced circulatory changes induced by the former, make it reasonable to regard syphilis as the cause of the large percentage of cases of valvular heart disease, which we find associated with tabes.

Thyroiditis as a Complication of Anginæ.—Four cases, in which there appeared to be some direct connection between these two conditions, are reported by W. Lublinski (Berl. klin. Woch., Oct. 12, 1903). They presented the symptoms of a moderate angina, with little rise of temperature. After the latter had almost declined, a sudden rise again occurred on the fifth or sixth day, accompanied by a painful, acute swelling of the thyroid glands. The pressure symptoms were not marked, but there was a considerable acceleration in the pulse rate. The swelling disappeared gradually in from two to eight weeks. In other cases, previously reported, suppuration always took place, and its absence in the author's cases may be explained by assuming that the swelling was of a rheumatic origin. The most relief was afforded by ice applications, followed later on, when the acute process had subsided, by a mild iodine ointment.

"Orthotic Albuminuria."—This term has been applied to that form of cyclical albuminuria which depends on the change of position from the horizontal to the vertical or vice versa. O. Jacobson (Berl. klin. Woch., Oct. 5, 1903) has made a careful study of a number of such cases and has just published the results of his observations. He believes that there is an intimate connection between this form of albuminuria and that associated with the time of puberty, in which a hereditary neurotic tendency plays an important rôle. Almost all the cases he saw were about the age of puberty, presented a pale, flabby appearance, and in a number of instances were markedly neurasthenic. One of the main factors in determining the diagnosis was the fact that albumin was entirely absent in the urine voided during the night. It seems that the albumin invariably appeared after the patient was up, and subjected to a certain degree of fatigue or exertion. He observed, however, that continual standing or slovenly walking was more apt to call forth this symptom than walking undertaken with a certain amount of interest and energy. He explains the sudden appearance and disappearance of the albumin in the urine by assuming that the easily disturbed nerve stability in these patients produces varying changes in the secretory function of the epithelium of the urinary tubules.

Relation of the Status Lymphaticus to Sudden Death.—A valuable addition to the recent literature of this subject is the paper just published by Geo. Blumer (Johns Hopkins Hosp. Bull., Oct., 1903). His views are based on nine cases of sudden death occuring in infancy and childhood, and on the study of the available literature, especial attention being paid to the histology and bacteriology of the condition. He concludes that the status lymphaticus is a definite pathological entity and is probably associated with, if not due to, a condition of intermittent lymphotoxemia. It may be associated with sudden death, probably as a result of lymphotoxemia alone in some cases, or as a result of the action of toxic, physical or psychic injuries, which are rendered much more powerful than usual by the predisposing action of the lymphotoxemia. In some cases the sudden death is undoubtedly mechanical and due to asphyxia from pressure of the enlarged thymus on the trachea.

Cause and Treatment of Various Kidney Conditions.—In a discussion of several clinical features which result from kidney and genito-urinary lesions, W. H. Thomson (Med. Rec., Oct. 17, 1903) has given some very practical hints in regard to therapeutics. He suggests that the high tension pulse of nephritis is due to an agent in the blood, similar to, if not, adrenalin, which causes kidney shrinkage and diminished urea excretion. The effects upon the circulatory apparatus in nephritis are exactly similar in kind to those caused by the intravenous injection of adrenalin. The possibility of the suprarenals being stimulated to increased secretion in cases of chronic nephritis is offered. Besides the increased blood pressure, investigation has shown that the suprarenal extract has a wonderful effect in causing a shrinkage of the kidney itself and naturally a diminution of urea excretion. In the treatment of cases manifesting extreme arterial tension and overacting heart when the ordinary vaso-dilators prove inefficient, as they do so frequently, the tincture of aconite in doses of five minims every three or four hours is often very beneficial, the urea at once being very much increased. He also describes a class of cases among women especially manifesting the symptoms of some nervous disorders and usually diagnosed as neurasthenia or hysteria. No organic lesions are found, but if the urine is carefully examined the excretion of urea will be found to be far below the normal. It is believed that digestive derangements are frequently the cause of this inhibition of urea elimination, just as normally the intake of food stimulates the excretion of urea. They usually feel worse in the morning, and the pulse is of low tension. It is believed that a bi-weekly dose of blue pill alternating with the pulv. glycyrrhizæ Co., and the steady administration of intestinal antiseptics, along with the regulation of the diet will in time relieve them of their multitudinous ner-

vous symptoms, and more surely than the nervines. Among the intestinal antiseptics he has found the best results from ten-grain doses of sodium or ammonium benzoate, with the same of phenol bismuth, or salve, with castor oil in shellac-covered capsules. A case of chronic spermatorrhea in a married man, resisting all methods of treatment ordinarily employed, is described. He had become almost a nervous wreck when a T-bandage was applied and a firm cylindrical pad two inches in diameter and covered with chamois skin was placed against the perineum and held in position by the bandage. The improvement was very marked in this instance, and the same method of treatment is recommended for the annoying cases of too frequent nocturnal emissions.

Treatment for Wryneck.—The etiology of this condition is by no means clear in the majority of cases, but organic causes are sometimes found and require appropriate measures. In the idiopathic cases we frequently express our ignorance by saying that the torticollis is due to irritation of the nuclei of the neurons. L. K. HIRSHBERG (Maryland Med. Jour., Oct., 1903) reports a method of treatment which he has employed in several idiopathic cases with excellent results. The Faradic current was applied daily for five minutes by placing the positive electrode over the wrist and applying a roller negative electrode over the healthy sternomastoid and upper fasciculus of the trapezius on the unaffected side. An internal treatment of two drops of liquor potassii arsenitis was continued three times a day during a considerable period. Improvements in each case began at once, but it required some time before complete recovery was reached.

Fat in Blood and Organs.—Fat is a normal constituent of the blood and organs, even in stillbirths, where no food has been taken into the alimentary canal. According to T. RUMPF (Virchow's Archiv, Vol. 174, No. 1), it is very difficult to determine the normal figures for the blood, since the amount is much larger after a meal than before, and the body possesses no organ which regulates the amount like the liver does for sugar. Diabetic coma does not seem to be accompanied by excessive lipemia, but high figures were obtained in arteriosclerosis and low ones in interstitial nephritis and tuberculosis. The heart and peripheral muscles may contain up to 16 per cent. of the dry residue, the liver 19.6 per cent., but in alcoholism and advanced tuberculosis as much as 56.6 per cent. was obtained. In the kidneys, the fat is increased in congestion and interstitial nephritis; for the spleen and brain no constant figures could be obtained.

Croupous Pneumonia Complicated by Pneumococcic Endo- and Pericarditis.—Pericarditis and endocarditis, complicating pneumonia, are seen so rarely that some of the authors attach no importance to such a complication. In fact, out of a grand total of 5,738 cases of croupous pneumonia, Von Brach hardly found .2 per cent. and .5 per cent. of them complicated by endo- and pericarditis, respectively. There occur undoubtedly some epidemics of pneumonia, in which this complication is more frequent than in others; then pregnancy predisposes to it, as well as preceding valvular disease. The causative factors of cardiac implications are most frequently the Talamon-Fränkel pneumococci, at times also the streptococci, and rarely also other microorganisms. The prognosis, always serious, and frequently fatal, becomes very grave when purulent meningitis supervenes upon the endocarditis. The case reported by SACHATZKY (Roussky Vrach, Oct. 4, 1903) was that of a croupous pneumonia in which, on the third day after a typical crisis, the patient began to have chills followed by a temperature of 40° C. This was accompanied by a gradually increasing weakness and paleness of the skin entirely out of keeping with such a temperature. Examination on the fifth day elicited a much wider area of cardiac dulness than was normal, and the appearance of a peculiar systolic murmur at the apex, and somewhat variable at the base and aorta. To these symptoms there was soon added a distinct friction sound of a pericardial nature. The pulse grew more and more frequent, and from dicrotic became hyperdicrotic. There appeared later on undoubted symptoms of pulmonary infarction, such as cough and mucus tinged with blood, and bronchial breathing, under the fifth and sixth ribs along the right mammary line. Later the urine was found to contain some blood and albumin which led to the suspicion of an infarction in the kidneys. Patient died on the fourteenth day of the disease from cardiac paralysis. The findings at the autopsy substantiated fully the antemortem clinical diagnosis.

A New Gastric Phenomenon in Migraine.—As the result of careful clinical observation, MANGELSDORF (Berl. klin. Woch., Nov. 2, 1903) claims that there is a regular and well-marked increase in the size of the stomach during an attack of migraine or epilepsy. He determined the outline of the stomach by percussion, after inflating the same when necessary, both during and after the attack, and controlled these findings by observations made during the intervals when the patient was well. This dilatation includes all parts of the stomach and subsides after the attack. In the course of time atony of the stomach results, followed later on by a variety of gastric and intestinal disturbances. Among 409 cases afflicted with migraine, only one presented a normal condition of the stomach, as regards this phenomenon, and in this instance the trouble had only been present a short time. Examination of a large number of patients suffering from other nervous or cerebral disorders failed to disclose this symptom, with the exception of those which were the subjects of idiopathic epilepsy. He does not attempt to explain this phenomenon, but notes that in all these cases where special attention was directed to treating the gastric atony, the migraine rapidly improved.

Cause of Milky Ascites.—While studying chylous ascitic fluid, J. JOACHIM (Münch. med. Woch., Nov. 3, 1903) was unable to detect any fat to account for the milkiness. He then subjected the proteid constituents of the fluid to an accurate analysis and found it rich in globulins. By solutions of ammonium sulphate of different saturation, the globulins were separated into euglobulin and pseudoglobulin. From the latter, lecithin could be split off, and it is probable that the loss of transparency is due to this combination.

Alkaptonuria.—In the condition known as alkaptonuria the urine turns brown rapidly when exposed to air and upon the addition of alkalies, while chloride of iron will give a green color and ammoniacal silver, and Fehling's solutions are reduced. It is not difficult, however, to distinguish such urine from diabetic urine, as it does not reduce bismuth nor turn the plane of polarized light, or ferment. The condition is generally congenital, the parents of the patients are often close blood connections, and there seems to be a close relation to that pathological lesion known as ochrinosis, marked by a dark pigmentation of the cartilage, and occasionally of the interna of the aorta and endocardium. L. LANGSTEIN and E. MEYER (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 1 and 2) find that the acids which occur in the urine are derived from the tyrosin molecule of the ingested albumin, and also from the albumin of the organs, since with proteid-free diet the peculiarities of the urine did not disappear.

SATURDAY, DECEMBER 5, 1903.

THE BREEDING OF GIANTS.

France, who is nothing if not hysterical, is now laboring under the throes of a severe attack of nervous dyspepsia over the problems of national decay and race suicide. This is merely an exacerbation of the seizure of the last year, when the admitted degeneration of her lower classes was attributed to the deleterious effect of the constant use of adulterated cordials and synthecated aperitifs—which, according to their own statistics, seemed to be filling their jails with degraded criminals and their insane asylums with duly qualified patients. This, however, does not account for the decrease in her birth-rate, which appears to have been due largely to the proverbial ounce of prevention, and which, when associated with what might be called domestic physiology, only goes to show that a little knowledge is a dangerous thing, particularly when it affects a national issue.

The remedies that have been prepared to arrest this increasing degeneration are numerous, and their Chamber of Deputies has been flooded with bills, all of which are frankly ingenious and some of which are gallically unique. Thus one learned legislator, who, though on pleasure bent seems, like John Gilpin, to be possessed of a frugal mind, proposes the offering of prizes for large families, and the remission of taxes to the happy fathers of many sons—the deficit of revenue thus occasioned being made good by an increased levy on the unblessed paterfamilias and lonely bachelors. Another interesting suggestion is that unmarried men shall be ineligible for official positions under the government, or municipalities, while the latest bill introduced, provides that married men and the fathers of children, shall be exempt from military service, and that the French army shall be limited to bachelors only.

All these measures, however, even if they were successful, would only tend to enlarge the number of births, while they would not improve the virility of the nation, or increase the strength of the individual. It is a question of quality rather than quantity, and at the best, the results of such legislation would only serve as an object illustration to the address of Dr. E. Benjamin Andrews, lately delivered to the Delta Epsilon Society, in which he begged President Roosevelt "to take early occasion to amend his plea for swelling the census, by urging quality of population as more of a desideratum." This, however, seems to really be one of the things that they do better in France, for some time since, Count Alfred de Pierrecourt left a legacy of $2,000,000 to his native city of Rouen to pay the expense of the propagation of giants. The will was contested by his heirs, who naturally enough did not see the necessity of having giants on the earth in these days, particularly when they were to be bred, raised, fed and clothed at their personal expense. The courts, however, sustained the will to the extent of endowing the Brobdingnagian experimenters with a quarter of the estate, so that an institution has been established with an income of $500,000, under the supervision of the municipality, for the culture of giants and the production of monstrosities.

The trustees are to search the four corners of the globe for men and women of large stature, and are to pair them off in couples and place them in the homes on a farm near Rouen. Neither race nor language is to be taken into consideration, and the fact that Bridget has never seen Hans has nothing to do with the case. Personal predilection does not enter into the spirit of the scheme, and she is to be torn from her native land with hardly enough of the soil left clinging to the roots to favor the transplantation, provided only that she has the necessary girth to balance the stature of the opposing and unknown party of the second part.

That there are difficulties in the path of the conscientious trustees is apparent. Wild birds will seldom sing in cages, and the production of giants, while you wait, is a new field of industry. Months waxed and moons waned, but Bridget had not laid her lofty head on Hans' towering shoulder while whispering confidential somethings in his vast and ponderous ear, and there were no tidings, as Nestor says, "Of the baby figure of the giant mass of things to come."

France was in despair. The importations were a failure, and Ribot's law of like begetting like, forbade the hope of any successful experiments with the domestic article. At this juncture came the announcement from America—like a sunbeam through the vapor—that one of the professors at the University of Chicago had been fortunate enough to discover the food of which giants are made, and that he had succeeded by its use in doubling the size of white rats. France went mad. The medical societies discussed it, the boulevards rang with its echoes and the journals were full of "M. le bon professeur Americain, Esquire, M.D., de Chicago," who would raise the glory of France until it was "six foot one way and five foot the other, and weighed four hundred pounds."

That their confidence is not misplaced and that their expectations are reasonable seems true. If the "professor" has done this to the rats, what could he not accomplish with a lot of French sansculottes, if their bones are as yielding as the conscience of Gaston, and their skin as flaccid and lax as the morals of Alphonse?

As to the discoverer of this food, his path lies open, free and fair for him to France. Americans are already large enough, and it is a pity to waste this "raising powder" on rats—be they white or gray. *A bon chat, bon rat,* and we have "foods" in plenty. Foods for babes, "foods for brain workers," foods for every sort and condition of men, and for each individual function that dwells therein.

"To-day no credit comes to you
For being noble, wise or great.
The advertisers say it's due
Entirely to the 'foods' you ate."

JEAN ASTRUC, A FORGOTTEN MEDICAL WORTHY.

It is probably the fortune of very few medical men to acquire enduring fame, and yet to be forgotten in their own profession. But such has been the fate of Jean Astruc. The name of Astruc is indelibly associated with the history of the higher criticism of the Hebrew scriptures, while his medical writings, which brought him much contemporary fame, are buried in our medical libraries among the forgotten tomes of the eighteenth century. The subject should not be without interest in the present age, which shows a growing curiosity to resurrect the names of the medical worthies of the well-nigh forgotten past.

Astruc was a French physician of great learning at a time when physicians were still renowned for their wide acquaintance with letters. He was born in 1684, studied at the University of Montpellier, and eventually held chairs successively at Toulouse, Montpellier and Paris. His teaching attracted many students, and his writings were voluminous. His chief work was *De Morbis Venereis libri sex*—a work which was translated into English and enjoyed a great vogue. He also wrote on obstetrical and medical subjects, and died at the advanced age of eighty-two years, after a life devoted to letters and to medical science.

All this would not, however, have preserved the name of Astruc, and it is one of the curiosities of literature that this learned physician owes his place in the realm of letters not to the labored treatises which he contributed to medical science, but to a small monograph which had no relation to medicine, and which its author probably regarded as among his least important works. This inconspicuous book was entitled *Conjectures sur les memoires qui ont servi â Moise pour écrire la Genése*—a book of which it may be said that it was pregnant with an idea of almost unsurpassed importance in modern literary criticism.

In this epoch-making book the author pointed out the fact that the cosmogony in the first two chapters of the book of Genesis was in two distinct accounts, written by different authors, and that the author of the first account (Gen. 1—1 to 11—3) always uses the Hebrew word *Elohim* for the deity, while the author of the second account (Gen. 11—4 to 11—25), always uses the word *Jahveh.* This hint or suggestion of such seemingly little importance, was subsequently recognized as the key to unraveling the composition of the earlier Hebrew scriptures, and has been adopted by all subsequent scientific critics in that most fruitful analysis, which is known as the Higher Criticism. Astruc had detected, in other words, the criteria by which the separate records of the *Elohist* and the *Jehovist* could in a large measure be recognized. The learned German scholar, Wellhausen, has said of Astruc that

he had the merit of opening the true path of this investigation of the Hebrew scriptures.

While this subject of Biblical criticism is in one sense outside the limits of medical science, it is, in another sense, of interest to all physicians who care to keep informed about the methods of science as applied to the unraveling of old documents which have had such a stupendous influence in opposing a true scientific conception of the universe. Moreover, the fact that one of the pioneers in this research—and one who contributed the most fruitful method—was a member of the medical profession, makes this interest all the more natural and inevitable. Astruc builded better than he knew when he turned from studying venereal diseases to study the composition of the book of Genesis. It is indeed a strange thought that this accomplished French physician of the old régime should have contributed, out of the fulness and wideness of his literary wealth, a small book in Hebrew criticism which will probably keep his memory green long after his venereal writings are forgotten.

ECHOES AND NEWS.

NEW YORK.

Plans for New Willard Parker Building.—Plans have been filed with the Department of Buildings, Manhattan, for a new six-story and basement laboratory and dormitory at Sixteenth street, east of Avenue C, for the use of the proposed new Willard Parker Hospital. The fifth floor will contain a library, and two floors are to be devoted to dormitories. The building will have a façade of ornamental brick, and is estimated to cost $100,000.

New Hospital for Staten Island.—St. Vincent's Hospital, a branch of St. Vincent's Hospital in Manhattan, located at the corner of Bard and Castleton avenues, West New Brighton, S. I., was formally opened on Friday last. Judge Albert Reynaud, in the address of the evening, said the Sisters in charge will not consider either creed, nationality or condition. The first ambulance service Staten Island ever had will be maintained. The hospital contains forty-one rooms, and accommodates about 200 patients. Sister Clement Marie, who had been attached for forty-nine years to the main hospital in Manhattan, will be in charge of the Staten Island branch. The property around the hospital, 257 city lots, was bought for $35.000.

Endowed Beds for Post-Graduate Hospital.—New York Lodge No. 1, Benevolent and Protective Order of Elks, is about to endow in perpetuity, at an expense of $15,000, two beds in the Post-Graduate Hospital, at Second avenue and Twentieth street. The hospital agrees to place the beds in a private room, to give the lodge the right to say who shall occupy them, and also to give these patients verything they need without additional expense. The money is to be paid in installments within a period of eighteen months. There has been subscribed already $4,700. There are only 1,300 members in the lodge, which in the last thirty-five years has given $220,000 to relieve sickness and distress.

Stamping Out Consumption.—The Charity Organization Society Committee on the Prevention of Tuberculosis is again circulating an appeal for funds to be used in checking the ravages of consumption in this city. Among the special needs which will have to be supplied, chiefly by private initiative, the Committte places emphasis on the following: Private sanatoria should be provided for patients who can afford to pay a moderate amount, and they should also be endowed sufficiently to provide for absolutely free treatment in exceptional cases. Relief funds should be supplied for the relief of indigent consumptives in their own homes until sanatorium or hospital accommodations are provided, and for patients who, on competent medical advice, can safely and with advantage to themselves and their neighbors, be treated at home. There are some instances in which the payment of board in private families outside the city is advisable, and relief funds should be provided for this purpose, especially in the interval pending the enlargement of sanatorium and hospital accommodations. Special dispensaries or clinics for the treatment of patients living at home are desirable. The presence of persons suffering from various forms of tuberculosis in general dispensaries is objectionable in the interests both of themselves and of other patients. Seaside sanatoria for scrofulous and tuberculous children are also needed, to which teachers should be attached, so that the intellectual development of the children need not suffer. An agricultural colony is desirable, where cured patients discharged from the sanatoria may find outdoor employment for a time. The education of the public in the means of prevention, and in those facts concerning the cure and treatment of the disease which are of interest and of value to the general public, is one of the essentials to the stamping out of the disease.

The New Medical Inspector of Hospitals and Retreats for the Insane and His Duties.—The New York State Commission in Lunacy had the following law passed at the last session of the Legislature: "The commission in lunacy may also appoint a medical inspector, who shall be a well-educated physician, a graduate of an incorporated medical college, and who shall have had actual experience in an institution for the care and treatment of the insane. Such inspector shall receive an annual salary of $3.500 and all his actual and necessary traveling expenses incurred by him in the performance of his duties, which shall be audited and paid in the same manner as the other expenses of the commission. He shall, subject to the direction of the commission, visit and inspect the several State hospitals and other institutions for the insane which are subject to the supervision, visitation and inspection of the commission. He shall, subject to the direction of the commission, make an examination, so far as circumstances may permit, of the patients confined in such hospitals and institutions, especially those admitted thereto since his preceding visit, giving such as may request it suitable opportunity to converse with him apart from the officers and attendants. He shall perform such other duties as may be prescribed and directed by the commission."

In accordance with this law, Dr. W. L. Russell, first assistant physician at the Willard State Hospital, was selected from a list furnished by the Civil Service Commission of physicians eligible to be superintendents of State hospitals, and on October 1 duly appointed medical inspector.

The character of his duties will be seen from the following outline which has been sent to the twenty-five licensed retreats for the insane in the State: The Medical Inspector shall make visits to the licensed private retreats for the insane at least once in two months, and oftener when deemed advisable by the Commission.

The scope of his inspection and report will include the following points:

Name of retreat.

Licensed for how many patients?

Number of patients—male voluntary, female committed. Total.

Number and names of physicians.

Number and names of ordinary attendants.

Number and names of trained attendants, with name of school of graduation in each case.

Note general appearance of attendants as to dress, conduct and apparent qualifications.

Number of servants.

He shall see all the patients present, both voluntary and committed, reporting to the Commission the names of any requiring special attention.

He shall write in his report the names of patients admitted since the last visit and the diagnosis.

Inquire into the method of treatment of acute cases, and the facilities for the treatment of maniacal excitement in acute and chronic cases.

Ascertain character of restraint used, if any. Reasons for use of restraint. All restraint apparatus on the premises to be exhibited to the Inspector, who will make a list of the same.

Is seclusion used? Number and names of patients found in seclusion.

Reasons for seclusion.

Classification of patients. Are sexes sufficiently separated?

Ascertain the adequacy of fire protection and fire-escapes.

The Inspector should visit all parts of the premises, all rooms, wards, closets, attics, basements, kitchens, stables and outhouses, and report on the general condition of buildings, furnishings and grounds.

Examine into sanitary conditions: Water supply, sewage disposal, number of bath-rooms and frequency of bathing patients, number of water closets, cleanliness, ventilation and lighting of toilet rooms, condition of clothes rooms, condition of mattresses, pillows and bed linen, hydrotherapeutic apparatus.

Examine medical certificates, histories and registries of admissions, transfers, discharges and deaths. Read commissioners' book and note whether suggestions made therein have been carried out. Ascertain whether any scientific work is done, such as methodical examination of blood, urine, etc., and number of autopsies performed. Report on dietary, amusements and occupation of patients. Make a minute of new construction in improvements contemplated. Enter in commissioners' book a minute of the condition of the house and patients. His inspection of the fourteen State hospitals includes features similar to those noted above for the private institutions. The work of the Medical Inspector supplements the work of the lunacy commissioners, but does not in any way diminish their duties. They are still required to make their usual semi-annual visit to the hospitals, both private and public. The more frequent inspections by Dr. Russell will keep the Commission constantly in touch with the institutions under its charge, accelerate attention to repairs and betterments and tend to the better safe-guarding and welfare of the patients.

PHILADELPHIA.

Hospital Damaged by Fire.—A recent fire in the out-patient department of the Children's Homeopathic Hospital, Franklin and Thompson streets, damaged the building to the extent of $4,000. It threatened for a time to ignite the main structure and caused the removal to other wards of 25 children.

German Hospital Donations.—At the annual donation day of the German Hospital held on Thanksgiving Day, 5,000 patrons visited the wards. The donations aggregated $9,000 in cash and $2,500 in merchandise.

New Methods of Disinfection.—Measures to remove some of the objections to the present methods of disinfection and fumigation of smallpox premises have been provided for by Councils and will be put in force in a few weeks. Temporary buildings for the disinfection of persons found in houses with smallpox patients will be erected outside of the Municipal Hospital grounds, this doing away with the necessity of taking such people within the hospital enclosure. In those instances where facilities for such baths are contained in the houses, tablets of disinfecting materials will be supplied and the well persons allowed to take their baths in the house, going immediately to those parts which have been disinfected. This is, of course, possible only in large houses. Instead of taking clothing and bedding to the hospital for disinfection, two large portable disinfecting wagons are to be constructed. They will be taken to the doors of the infected house, the goods placed in them and disinfection accomplished by means of live steam and formaldehyde.

Report of State Board of Health.—An important feature of the meeting of the State Board of Health held at Pittsburg, November 27, was the annual report of the Secretary, Dr. Benjamin Lee. The larger part was devoted to the consideration of smallpox, of which there was during the year, in Pennsylvania, 6,504 cases and 503 deaths. The largest number occurred in Pittsburg, where there were 1,234 cases and 238 deaths. Dr. Lee directed particular attention to the inefficiency of maintaining ordinary hygienic conditions and personal cleanliness alone as a preventive of smallpox. The Board early in the present epidemic often received urgent appeals from physicians who feared the results if smallpox appeared among crowded settlements of ignorant foreigners, who live in filthy surroundings. It was found, however, that the disease did not spread among these foreigners, but among the enlightened Americans who were not vaccinated. Dr. Lee said that the prominent establishments in Pennsylvania for the manufacture of vaccine virus had been highly commended by the examining officials of the United States Public Health and Marine Hospital Service.

Epidemic of Typhoid Fever in Butler.—An extensive typhoid epidemic is at present prevailing in Butler, Pennsylvania. More than 1,500 cases out of a population of less than 13,000 have occurred and 30 deaths have occurred up to the time of writing this letter. The source of infection has been found to be in the water supply of the city. Heavy rains had destroyed the new reservoir and an old one had been used. Finally the filtration plant broke down and water was taken directly from the creek. Soon after this typhoid appeared. Four of the physicians of the city are down with the disease. Appeals for aid have been made to nearby towns and, unofficially, to Philadelphia. Dr. F. C. Johnson, assistant chief resident physician at the Philadelphia Hospital, was sent by Director Martin to Butler to determine the

conditions there and decide whether relief should be sent from this city. An extraordinary meeting of the State Board of Health was held in Butler immediately after their meeting in Pittsburg. Secretary Lee says that the epidemic is the result of the failure of physicians to make weeky reports of contagious diseases. The disease had been in progress for some time before the health authorities were cognizant of its extent.

Smallpox Continues to Increase.—Smallpox is rapidly taking on the proportions of an epidemic in this city. For the week ending November 28 the new cases numbered 70, and for the 48 hours following they numbered 40. The largest number of the cases are located in the sections north of Market street and west of the Schuylkill. The spread continues in spite of the extra precautions that have been taken during the month of November. Double quarantine, front and back, has been placed upon houses containing the disease and the interior subjected to several fumigations before removing quarantine. Upward of 300 cases are now under treatment at the Municipal Hospital, additional nurses and attendants being made necessary. The sixth case among the colored religious fanatics who refused vaccination occurred November 30.

The Control of Contagious Diseases.—The meeting of the Philadelphia County Medical Society, November 25, was devoted entirely to a consideration of the report of a committee appointed to suggest methods for the control of contagious diseases by the Municipal authorities. The report was presented by Dr. Alfred Stengel who stated that the committee had prepared it after investigations of the methods in New York, Boston, Baltimore, St. Louis and Chicago. Among the recommendations was one making the reporting of contagious diseases the duty of the household in which they occur. This should be done on postal cards furnished by the Board of Health and distributed by physicians. Physicians would still be required to report all notifiable diseases as heretofore. Among the new diseases to be placed on the notifiable list were mentioned measles, German measles, plague, anthrax, glanders, rabies, and tetanus. They suggested that physicians instead of householders should report cases of laryngeal and pulmonary tuberculosis. Another suggestion was that quarantine of cases of diphtheria should be removed after a period of two weeks from the time of clinical recovery without making cultures from the throat. This method might occasionally allow the escape of a contagious case, but if negative cultures are depended upon the quarantine law will often be evaded and the hardship of detention be enforced upon many people who are not capable of spreading the disease. The discussion of the report brought out many diverse opinions regarding the recommendations. Dr. A. C. Abbott raised the question of placarding houses, stating that the practice was an annoyance and was not of great service in keeping people away from such houses. Perhaps smallpox and plague placarding might be allowable, but there are perhaps better ways of managing even them. He would recommend a special corps of sanitary police for enforcing quarantine. Dr. Abbott thinks it is a mistake to recommend the clinical instead of a bacteriological test for the raising of quarantine of diphtheria patients. After a long and spirited discussion the report was referred back to the committee for revision. Director Martin stated that it was the desire of the Health Department to obtain opinions from the County Medical Society and the College of Physicians regarding the best methods of handling contagious diseases. When these were obtained the Department would try to enforce the recommendations as being those that were practicable. He stated that it was easy for executive departments to institute a set of regulations that were theoretically ideal and yet impossible to actually carry out. Hence he wishes the united opinion of the profession as to methods that can be carried out even though they be theoretically imperfect. When the physicians of the city unite on certain definite plans the department is ready to assist in putting them into action.

Medical Inspection of Schools in Philadelphia.—In June, 1898, a committee of the Public Education Association brought to the attention of the Board of Health the control obtained over contagious diseases in other cities by a careful inspection of what have proved to be the centers for the spread of contagion, the public schools. A resolution was passed on June 7, 1898, by the Board of Health, directing the 15 Assistant Medical Inspectors to visit one public school each day in their respective districts. This inspection commenced on June 16, and during the following winter, from October, 1898, to February, 1899, a period of 13 school weeks, a large number of contagious cases were found in the schools by the Inspectors. The John Bartram School, Mt. Moriah Lane and Greenway avenue, Fortieth Ward, furnished a test case for the system. In September, 1898, it was threatened with an epidemic of diphtheria. Of 13 cases in the ward, 11 had been attending that school. Investigation by the Board of Health showed that children from a certain house had been attending the school with "sore throats." The family being Christian Scientists, no physician had been called. Examination proved them to be suffering from diphtheria. An investigation of the absent list of the school developed 2 other cases of diphtheria. The school was at once fumigated, and daily visits of the Medical Inspector placed the school under surveillance until the disease had disappeared. In December, 1899, this Association went before Councils with a plea that the Health Board should be given funds to extend the inspections to all schools, both public and parochial, and should be given a corps of Medical Inspectors large enough to permit of daily visits to all of the 325 buildings of the public schools, as well as the 28 of the parochial schools. But almost immediately thereafter, the Board of Public Education devised and instituted a volunteer service under its own control. This service lasted from January 1 to November 1, 1900. It was incomplete and imperfect because unorganized and unpaid: yet there were discovered a total of 5,876 cases of illness of which 3,446 were contagious cases and 2,430 non-contagious. In addition, there were many non-contagious cases that were not reported, and many children who were excluded from school without report of their cases. Among these the reports emphasized 12 cases of well-developed diphtheria, 4 of scarlet fever, 112 of measles, 115 of mumps and 212 of lice; 1,001 cases of badly defective eyesight were reported in addition to 397 cases of contagious eye diseases. In our own city the past inspections have made an impression on parents, teachers, Sectional Boards and the Board of Public Education. The Department of Health and Charities is now anxious to increase its force of Assistant Medical Inspectors to a number that will permit them to include in the daily duties visits to the schools, which are the centers of the spread of contagious diseases. This meeting is intended to endorse and assist the Department in obtaining public recognition for its desire that the city practise the economy of the ounce of prevention, daily medical inspection of school children, rather than the pound of cure, which means a

full contagious hospital, schools closed for disinfection, sick children, and the work of the schools interrupted. The value of human life saved, to say nothing of the suffering, bereavements and diseases prevented, infinitely outweighs the comparatively trifling cost of a few additional Medical Inspectors.

Obituary.—Dr. William Shaw Stewart, one of the founders and ex-dean of the Medico-Chirurgical College, died suddenly of heart failure at his home, 1725 Pine street, November 25. Dr. Stewart was sixty-five years of age and had long been identified with the growth of medical science in Philadelphia. He graduated from Jefferson in 1860. He served throughout the Civil War as assistant surgeon. Dr. Stewart was instrumental in founding the Medico-Chirurgical College and for ten years was its Dean, being professor of obstetrics and clinical gynecology. He was professor emeritus at the time of his death.

CHICAGO.

Improved Milk Supply.—An improvement shown in the reduction of samples of milk below grade from 45 in every one hundred collected in 1893 to less than 8 in the hundred at the present time, is to be credited with a large share of the saving of children's lives between one and five years, the milk feeding period.

The relationship of the milk supply to infectious diseases of children is very intimate and work carried out by the Health Board of New York City in co-operation with the Rockefeller Institute is worthy of emulation and of the adoption of similar methods for the investigation of the conditions in Chicago.

Infectious Diseases.—Acute infectious diseases are fewest, but influenza shows signs of increased activity. Total deaths for the week were 467.

Appointment of Dr. Ruediger.—Dr. E. H. Ruediger of the Memorial Institute for Infectious Diseases, Chicago, has been appointed assistant in the Serum Institute, Manila, P. I.

Probert Fine.—It will be remembered by the readers of the MEDICAL NEWS that Arthur C. Probert, Vice-President of the Christian Hospital, was arrested on the complaint of Dr. J. B. Murphy and others on the ground that their names were being used without authority, on certificates of the hospital to induce other physicians to become members of the staff on payment of fees of varying amount, and was fined last week $500 and costs for the fraudulent use of the mails.

Salpingoscopy.—Dr. Joseph C. Beck read a paper on this subject before a recent meeting of the Chicago Laryngological and Climatological Association. This is a term given by Valentine to the method of examination of the ostium of the Eustachian tube and the nasopharynx by means of his salpingoscope, which is nothing more nor less than a small cystoscope. Hirschmann claims the priority of this instrument, and calls it the endoscope, for the purpose of examination of the nose, especially the ostia of the accessory sinuses. The various conditions the essayist uses this intrument for examining are as follows: (1) Acute salpingitis following and associated with an acute rhinitis, where the patient complains of a fulness in his ear; (2) acute rhinitis without the symptom of fullness in the ears, including hay fever; (3) acute otitis media non-suppurativa; (4) acute otitis media suppurativa; (5) chronic otitis media non-suppurativa; (6) chronic otitis media suppurativa; (7) in cases where he cannot place properly the Eustachian catheter or inflate with satisfaction; (8) in the use of a bougie; (9) adenoids; (10) chronic postnasal catarrh; (11) marked hypertrophies of the posterior ends of the inferior and middle turbinated bodies; (12) atrophic rhinitis; (13) examination of the ostium maxillaris in sinus disease, where the anterior half of the middle turbinated body had previously been removed; (14) the roof of the nose in the same conditions; (15) antrum of Highmore through the opening of the jaw; (16) the act of swallowing and speaking in the healthy subject and in one with paralysis of the soft palate; (17) tuberculous and syphilitic laryngitis, etc. The larynx may be examined by means of this instrument, being situated in the nose, the prism turned downward, and while the patient is instructed to breathe freely through the nose, one can see clearly the chink and sometimes the vocal cords. Again, it may be used in the mouth, as Valentine and others have used it, particularly in young individuals, and get a much larger and clearer image of the larynx. The author's conclusions are: (*a*) That it is an aid in diagnosis; (*b*) it is absolutely necessary to familiarize oneself with the technic and learn the comparative sizes of the structures; (*c*) its use is principally of value in the nasopharynx in examination of the ostium tuba.

Spastic Dysphonia.—Dr. John Edwin Rhodes contributed a short paper with this title. This term is applicable to any neurosis of the larynx which is characterized by difficulty in phonation. It is, so far as the larynx is concerned, a local condition rather than a disease, the lesion for which it is a symptom being one of the nervous system, and usually situated in the brain. It is a neurosis in which there is a spasm of the larynx, and a failure to properly coordinate its muscular action on attempts at phonation. In these cases on an inspection of the larynx a normal condition is found so far as appearances are concerned, while the respiratory function alone is taking place. However, as soon as the impulse to the muscles of phonation is sent along the efferent nerves there is an immediate spasmodic action of the larynx apparent, the voice being broken in a characteristic manner, but as soon as the attempt ceases the normal action of the larynx in phonation is resumed. The affection is rare, as MacKenzie has seen but 13 cases, although Lennox Brown believes that it is found more frequently, a statement with which most observers do not agree. The patient was a farmer, forty-two years of age, and gave the following history: His speech had been affected for twenty-three years, but had become worse in the last five years. Early in the history of the trouble there was an almost total loss of speech. The trouble seemed to begin rather suddenly as a cold, with loss of voice. As this was not restored after a time, he and his friends became alarmed. His family history shows the death of his mother from paralysis following typhoid fever at seventy-three years of age. Patient is of a nervous temperament, and has had several nervous breakdowns in the last few years. He is inclined to be morbid and constantly worries over his condition. There is a considerable loss of weight; from 140 pounds a few years ago and 125 pounds two years ago, his weight has declined to 119 pounds. He is rather anemic, having a pale, sallow complexion. His pulse is 72, and slightly unsteady. His temperature is a part of the time above normal, reaching 100.2° F. There is no cough, but some hacking and clearing of the throat. The appetite is good, but digestion is poor, and he complains of a miserable feeling in the bowels constantly. He is habitually constipated, and a constant user of cathartics. On attempts at phonation there is at

once a marked tremulousness of the voice. The words are broken and vibratory, more so at the very beginning of efforts to speak than when he has gotten well started; then the words are uttered more easily, some words having an even, clear tone, but most of them characterized by tremulousness; such use of the voice causes fatigue. When he is excited or a little embarrassed or tired, the trouble is more marked. The whisper voice is perfectly normal, and he can use it without fatigue for any length of time. There has never been any dyspnea. He has had nasal catarrh since childhood. The patient denies having had syphilis. There are a few enlarged follicles on the pharynx and some diseased crypts in the tonsils. The laryngeal structures show no evidences of inflammation. On attempts at phonation, the abduction is not delayed, but on the attempt at verbal utterance, the tremulousness of the cords is at once apparent. Tension is held for an instant only, when there seems to be a relaxation, allowing a fuller column of air to pass, throwing the vocal cords into vibration in their entire length. The arytenoids seemed fixed with no relaxation while this condition of tremulousness is observed. In the utterance of a single and prolonged note, there seems to be an uneven escape of the air column, an intermitting tension and relaxation. This condition is not apparent when he whispers. There are no evidences of this tremulousness elsewhere. There is none of it about the head, neck, or extremities, and it is not in evidence except when speaking. The reflexes are normal.

Skiagraphic Fallacies.—Dr. John A. Robison read a paper on this subject. He pointed out that the development of skiagraphic plates is more difficult than that of the ordinary plates. One must eliminate all sources of error intrinsic in the plate, the developing fluid, and the manipulation of the X-ray apparatus. He found quite a number of plates would develop more rapidly in certain spots than others. In one instance he was shown a plate where a dark spot over the region of the left kidney had been pronounced to be a renal calculus. He took two skiagraphs of this patient, and was unable to find the shadow. He persuaded the patient to secure another skiagraph from the first operator, who subsequently acknowledged he did not obtain the same result in his second plate. He has seen skiagraphs of lungs where the light areas seemed to prove the presence of pulmonary cavities, which light areas did not exist in subsequent plates. In the development of skiagraphs one has not the contrast of light and shadow, as in ordinary photography. The entire plate in the developing fluid speedily becomes dark, and it is easy to overdevelop the plate and obliterate the contrast between the lights and shadows. It is to secure the proper contrasts that experience in the exposure of the patient to the X-ray becomes necessary. It is only possible to secure good results by experience, and in medical skiagraphy the interpretation of the results can only be truthfully made by a physician, no layman having the necessary pathological knowledge to enable him to interpret the shadows cast by various pathological conditions. But granted that the technic has been perfect, errors may ensue from the wrong interpretation of the skiagraph. Two cases were narrated in point.

GENERAL.

Cause of Typhoid Fever at Williams College.—It has been determined by the authorities at Williams College, Mass., that the source of typhoid which recently developed among the students, and at one time threatened to become a serious epidemic, was a can of milk. The theory is that the milk was cooled in impure water, and that a little of the infected water accidentally got into the milk. The can in question did not come from a Williamstown dealer, but was brought from outside the town.

Cuba's Death Rate.—Statistics printed last week show that during 1902 the death rate in Havana was 21.9 per 1,000. There were 6,279 births and 5,832 deaths. The greatest number of deaths, 885, were from tuberculosis. There were 176 deaths from cancer and 469 from enteritis.

William Peirson Medical Association.—The following named physicians have been re-elected officers of the William Peirson Medical Association of Essex County, N. J., for the ensuing year. President, Thomas W. Harvey, M.D., Orange; First Vice-President, Richard C. Newton, M.D., Montclair; Second Vice-President, Joseph C. Young, Newark, N. J.; Treasurer, J. Hammond Bradshaw, M.D., Orange; Secretary, Richard D. Freeman, M.D., South Orange; Librarian, Henry A. Pulsford, M.D., South Orange; Council, the above named and Theron Y. Sutphen, M.D., Newark; Mefford Runyon, South Orange, and William B. Graves, East Orange.

Mississippi Valley Medical Association.—The thirtieth annual meeting of the Mississippi Valley Medical Association, will be held at Cincinnati, O., October 11, 12, 13, 1904. Dr. B. Merrill Ricketts has been elected Chairman of the Committee of Arrangements. The following are the officers of the Association elected at Memphis: President, Edwin Walker, M.D., Evansville, Ind.; President-elect, Hugh T. Patrick, M.D., Chicago, Ill.; First Vice-President, Bransford Lewis, M.D., St. Louis, Mo.; Second Vice-President, Geo. W. Cale, Jr., M.D., Springfield, Mo.; Secretary, Henry Enos Tuley, M.D., Louisville, Ky.; Assistant Secretary, S. C. Stanton, M.D., Chicago, Ill.; Treasurer, Thos. Hunt Stucky, M.D., Louisville, Ky.

The following resolution was offered by Dr. S. P. Collings, of Hot Springs, Ark., at the Memphis meeting.

Whereas, The value of perfect sight and hearing is not fully appreciated by educators, and neglect of the delicate organs of vision and hearing often leads to disease of these structures, therefore, be it

Resolved, That it is the sense of the Mississippi Valley Medical Association that measures be taken by Boards of Health, Boards of Education and School authorities, and where possible, legislation secured, looking to the examination of the eyes of all school children, that disease in its incipiency may be discovered and corrected.

The Government Hospital at Luzon.—According to the report of an officer serving in the Philippines, the hospital maintained there by the Government is in a flourishing and highly satisfactory condition. For three hundred years the Spaniards got no further than the recommendation for establishing a health station in the mountains of Benguet, which amounted to nothing more material than an indifferent discussion as to its site; but in 1902, shortly after the establishment of the Taft régime in the Archipelago a Civil Service Sanitarium was set up at Bagnio in the hilly region of Luzon. One of the difficulties, perhaps the chief difficulty, in starting an institution of this sort in the tropics is the matter of choosing a suitable location. In the lowlands one must always contend with the scorching days, sultry nights and pestiferous insects; while the highlands are often very little better and quite inaccessible. The latter condition is present in this attempt in some slight degree, but the hospital can be reached in something less than three days on horseback, a short journey as traveling goes in the Islands. A plateau three miles in circumference and lying 4,700

feet above sea level has been carefully laid out by a landscape gardener and on it the more permanent structures are to be erected. A natural advantage and one of very great importance is the soil of porous clay, while spring water of excellent quality can be readily obtained from the limestone hills. In 1902 a small pine house with a glass roof served to accommodate 8 or 10 patients, and in 1903 this was enlarged to provide for 50, with 5 cottages for special cases. Present appropriations allow for 20 new rooms and 7 new cottages. The Sanitarium is used also as a sort of hotel for those who wish to come up out of the heat and fatigue for a few days' rest. The daily temperature is 63° to 68° F., the nights are cool and blankets are required for sleeping. One dollar per day is charged to those who can afford it, while the more affluent can pay as much as $3.50 for subsistence and attendance.

Obituary.—Dr. Hawkins Brown, aged seventy-three, died at his home in Hustonville, Ky., of paralysis of the heart last Tuesday. He was an ex-President of the Kentucky State Medical Society, a surgeon of the First Kentucky Cavalry, and a medical officer of Gen. Stoneman's staff during the Civil War.

CORRESPONDENCE.

AMERICAN AND INTERNATIONAL CONGRESSES ON TUBERCULOSIS AND TUBERCULOSIS EXHIBITS FOR THE YEARS 1904 AND 1905.

To the Editor of the MEDICAL NEWS:

DEAR SIR: During the past few months I have been the recipient of a large number of inquiries concerning the various tuberculosis congresses (American and International) which have been projected for the years 1904 and 1905. The multiplicity of these various congresses and the similarity of their names leads naturally to great confusion. It would be really too great a task to undertake to answer in full and individually all the letters with which I have been honored. I therefore ask you to grant me the space to give the desired information in your esteemed paper, so that all the readers of the MEDICAL NEWS, who may be interested, will have a clear idea of the various congresses, their officers, and time and place of meeting.

It is announced that a congress on tuberculosis is to be held in St. Louis on October 3, 4 and 5, 1904, under the name of International Congress on Tuberculosis. Upon careful inquiries I learned the following facts about this congress: Mr. Francis, the President of the St. Louis Exhibition, has been approached by the officers of the American Congress on Tuberculosis, which was founded some years ago by Clark Bell, Esq., a lawyer of the City of New York, to sanction the holding of an international congress on tuberculosis in connection with the Louisiana Purchase Exposition. From a letter received from Dr. E. J. Barrick, of Toronto, Canada, the now President of this American Congress, I learn that Mr. Francis has appointed the above-mentioned Mr. Clark Bell Chairman of the Committee on Organization. Mr. Clark Bell is also the Treasurer and Chairman of the Executive Committee of the American Congress on Tuberculosis, season 1903-1904; a Mr. Samuel Bell Thomas, of 290 Broadway, New York, is the Secretary of the latter. The officers of the International Congress are not yet elected. I was desirous to learn the names of other medical men interested in this congress, and Dr. Barrick very kindly wrote me on Nov. 16 that he had asked Mr. Bell to furnish me the desired additional information, but nothing has thus far been received.

The other international tuberculosis congress announced is the one to meet in Washington, D. C., April 4, 5 and 6, 1905. It is to be held under the auspices of The American Congress on Tuberculosis for the Prevention of Consumption. The following is a list of the officers of this latter organization:

Honorary President, Dr. Henry D. Holton, Brattleboro, Vt.

Member, Executive Council, Dr. Chas. O. Probst, Columbus, O.

President, Dr. Daniel Lewis, New York.

1st Vice-Pres., Dr. E. A. Egan, Springfield, Ill.

2d Vice-Pres., Dr. Frank Paschal, San Antonio, Tex.

4th Vice-Pres., Dr. Irving A. Watson, Concord, N. H.

5th Vice-Pres., Dr. Chas. Wood Fassett, St. Joseph, Mo.

Secretary, Dr. George Brown, Atlanta, Ga.

Treasurer, Dr. P. H. Bryce, Toronto, Canada.

Before going further, I would like to call the attention of the readers to the difference in name of the two American congresses. The one is American Congress on Tuberculosis, the other The American Congress on Tuberculosis for the Prevention of Consumption.

The congress which was to meet under the name of Congres International de la Tuberculose at Paris from Sept. 26 to Oct. 1, 1904, has been recently postponed to the year 1905. The President of this Congress is Professor Brouardel, Hon. Dean of the Faculty of Medicine of Paris. The General Secretary is Dr. M. Letulle, Prof. agrege of the Faculty of Medicine, residing at 7 rue Magdebourg, Paris. This Congress will be divided in two sections, the medical and the social:

I. In the medical section the following subjects will be discussed: (1) New methods for the treatment of lupus; (2) new methods for the early diagnosis of tuberculosis; (3) comparative studies on the different forms of tuberculosis.

II. In the social section: (1) Etiological factors in tuberculosis; (2) value of different means for the treatment of tuberculosis; (3) the voluntary insurance and the mutual societies in the combat of tuberculosis.

The Congress will furthermore form a technical section under the name of Museum of the Congress.

There will be held during the coming year independently of the above mentioned congresses two tuberculosis exhibitions, one in Baltimore, Md., and the other in St. Louis, Mo. The Baltimore Tuberculosis Exhibition will be held in January, 1904, under the combined auspices of the Tuberculosis Commission, the State Board of Health, and the Maryland Public Health Association. Details are in charge of Dr. W. S. Thayer, president of the Commission; Mr. John M. Glenn, secretary; Dr. John S. Fulton, secretary of the State Board of Health, and Dr. Marshall L. Price. Dr. Henry B. Jacobs has been elected Chairman, and 250 prominent professional men and laymen have been asked to act as an advisory committee. A series of lectures will be given, the object of which will be to present the extent and effects of the disease in a striking manner. The pathological, hygienic, sanatorium and sociological aspects of the tuberculosis problem will be practically demonstrated by specimens, charts, literature, instruments, photographs and plans. All communications concerning the exhibition should be addressed to Dr. Marshall Langton Price, 10 South Street, Baltimore, Md.

The other tuberculosis exhibition will be held in St. Louis, in connection with the exhibition of Social Economy and under the Subsection of Hygiene, of which Dr. J. N. Hurty, of Indianapolis, is Superintendent. To avoid multiplicity of exhibits, Dr. Hurty has put himself in communication with the General Secretary of the International Bureau for the Prevention of Consumption at Berlin, Professor Pannwitz, so

that the exhibits which the European countries contemplate to send shall also come under his direction.

All indications point toward success of both exhibits, and it is to be hoped that they will fulfill their high purpose and at the same time be a credit to American physicians and hygienists.

Considering the various congresses I do not hesitate to express a feeling of deep anxiety. The first one mentioned, which, for reason of brevity, I will call "The Bell Congress," because it owes its inception to Mr. Clark Bell, has to my knowledge not the support of our best known men in the field of clinical medicine, hygiene, tuberculosis pathology, or tuberculo-therapeutics.

The second congress in point of time, which again for sake of brevity and clearness I may call the "Lewis-Brown Congress" (names of the President and Secretary), while it has many distinguished men of various State and Provincial Boards of Health among the members, has, like the Bell Congress, thus far not among them the men we are wont to look up to as leaders in movements of this kind. No such men as Biggs, Billings, Bowditch, Flick, Jacobi, Janeway, Klebs, Osler, Otis, Trudeau, Tyson are connected with this Congress.

What are our confrères across the water to think if they hear of two American congresses on tuberculosis, and each having an international one under its auspices? The European authorities found it best, instead of having a triennial congress, to have one more year to intervene. This will make the congress in Washington and the one in Paris convene in the same year (1905).

I hope this letter, which I address to the medical profession in America, will result in a satisfactory solution of this very complicated problem. If President Francis, of the St. Louis Exposition, desires that a tuberculosis congress shall be held in St. Louis, let him call to his aid some of the men whom I have mentioned as leaders in our profession. They will counsel with him on the advisability of such a congress, and if it is decided that one should be held, Mr. Francis can be assured that the best element of Europe and America will come to St. Louis to contribute to its success.

The officers and members of the Lewis-Brown Congress must realize that they cannot expect to have their international meeting in Washington to be successful, when, six months later, there will be an international congress in Paris. I hope that there will be enough patriotism and national pride for all interested to realize that two American congresses on tuberculosis is an anomaly, and that, if the St. Louis Congress is to be a success, it must be in the hands of medical men well and favorably known in this country and abroad.

As a solution of the problem I beg leave to suggest the following: During the Tuberculosis Exhibition in Baltimore next January, all interested should meet on a certain date on this neutral ground for the purpose of coming to an agreement about a single representative National or International Tuberculosis Congress, to be held in America. There, too, should be formed a National Committee on Tuberculosis, which is to be in touch with the international tuberculosis congress, which will convene in Paris in 1905.

16 West Ninety-fifth Street,
New York, Nov. 27, 1903.

S. A. Knopf, M.D.

The Urine after Splenectomy.—The following effects of ablation of the spleen upon the urinary secretion were noted by L. E. and F. Demoulin and J. Nicolas (Jour. de Physiol. et de Path. Gén., Sept. 15, 1903): A slight increase in volume, an increase in the content of urea, possibly to be attributed to a hyperactivity of the liver, a transient and slight augmentation of the chlorides and diminution of phosphates, and the absence of glycosuria or albuminuria.

OBITUARY.

DR. CYRUS EDSON.

Dr. Cyrus Edson, of New York, son of ex-Mayor Franklin Edson, died late Wednesday night in the Roosevelt Hospital from double pneumonia.

After an almost continuous attendance on his patients, one of whom had died of a violent attack of pneumonia last Saturday morning, Dr. Edson concluded to take a few days' recreation in the country. He was a member of the Larchmont Club and went there in the early part of the day, where he played golf until nightfall.

On Sunday morning he was found in bed greatly depressed from a severe chill; evidences of pneumonia soon became apparent and he was removed to Roosevelt Hospital without delay.

Dr. Edson was born in Albany on Sept. 8, 1857. He was educated first at a military school at Throgg's Neck, N. Y., and afterward at Columbia College, where he rowed in the 'Varsity crew. He was also a member of the famous Henley four.

Dr. Edson graduated from the College of Physicians and Surgeons in 1881 and was chosen by his class as Grand Marshal. In 1882 he was appointed Assistant Sanitary Inspector in the New York Health Department and was promoted through the regular grades to Commissioner. He was appointed by Gov. Cornell as Assistant Surgeon of the Twelfth Regiment on the staff of Col. Cruger, and served in this office for about one year, when he received an appointment on the First Division staff.

He was President of the Board of Pharmacy of this city and of the County of New York in 1893, and during his career he held the following positions: Chief Inspector of the Second Division in the New York Health Department, Visiting Physician to the Charity Hospital, Vice-President of the American Society of Public Analysis, and Secretary of the Committee on Hygiene of the New York County Medical Society.

Dr. Edson was also the author of many articles on medical and sanitary subjects and the inventor of useful surgical instruments. He was President and Director of the New York Pharmacal Company, Vice-President and Director of the Rapid Safety Filter Company, and a member of the St. Andrews and New England Societies, the Larchmont Yacht Club, and the Society of Medical Jurisprudence.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-urinary Surgery.

Stated Meeting, held October 21, 1903.

Dr. Howard Lilienthal, Chairman *pro tem.*, in the Chair.

Deformity of Penis Resulting from Operations for Relief of Hypospadias.—Dr. Howard Lilienthal presented a man, twenty-two years old, who had been admitted to Mount Sinai Hospital April 13, 1903, and discharged one month later, after an operation for the relief of a deformity which had followed ten previous operations for the relief of hypospadias. The patient had stated that the opening had been about three-quarters of an inch behind the end of the glans. When he was first seen by Dr. Lilienthal the deformity was such that it was difficult to recognize the organ as a penis. So far as his sexual function was concerned, he was apparently normal and he urinated very satisfactorily, although the stream passed in every conceivable direction. Of course, the cosmetic effect was bad. The first

operation performed upon him was a Beck and it appeared as if, when the urethra had been drawn through to the anterior part of the glans and stitched there, it had sloughed and, as it descended, it seemed to have drawn with it a portion of the glans which, when Dr. Lilienthal first saw him, appeared as an isolated fragment, entirely separated from the glans penis.

Extravasation of Urine, Due to Phimosis.—The patient, forty-five years of age, single, had always been troubled with tight prepuce, never having been able to expose the glans penis more than around the meatus. During the past few years, especially, the tissues have become thickened from frequent attacks of balanoposthitis, and some weeks previous to admission to Bellevue Hospital he contracted what was apparently a chancroid. Previous history of gonorrhea of some years' standing, uncertain. Micturition had been frequent, painful and attended with great effort and straining, until upon the early morning of the day of admission the patient found himself unable to pass anything, when, after pressure and straining, he felt something give way, with slight sensation of relief. A few hours after that time he applied for admission. When the doctor first saw him on the afternoon of the same day the whole penis was immensely swollen from an apparent infiltration, which extended back and involved the scrotum, to about the size of a large orange, giving a perfect clinical picture of extravasation from stricture, and as the penis alone, according to the patient's history, had been at first involved (the scrotum secondarily), and as he was rather heavy mentally as regards previous history as to clap, the doctor was under the impression at first that he was dealing with an anterior extravasation due to stricture, the House Staff having informed him that they had been unable to pass any instrument. The preputial opening was absolutely closed, but a dorsal incision over the glans liberated a large quantity of blood and urine, exposing to view a normal meatus, through which a No. 30 steel sound readily slipped into the bladder. The point where rupture had taken place was apparently just posterior to one side of the frenum. The incision made for the circumcision, passing through the part, which was readily made out in the fresh specimen, is difficult to find now, on account of the shrinkage due to formalin. Incisions were made in the scrotum, and the case made a normal recovery.

Retention of Urine, Due to Foreign Body in Bladder, of Uncertain Origin.—Widower, thirty-nine years of age. First attack of gonorrhea nineteen years ago, with no complications. Second attack, seven years ago, followed by posterior urethritis and cystitis. Micturition the following winter, being three or four times at night, increasing in frequency, until last February he was obliged to get up from ten to fifteen times, at which time he first noticed blood in his urine, *mixed, and never in clots.* When there was no blood, the sediment was marked. During March, an apparent exposure to cold caused an acute retention. Later on, incontinence, which lasted until the middle of April, when he was taken to a Dispensary, prescribed for, and again suffered from retention. He was then catheterized for the first time (no instrument of any sort ever having been previously passed), and a large amount of bloody urine withdrawn. A few hours later he applied for admission to Bellevue Hospital, still with retention. Examination of the urethra showed an obstruction beyond the cut-off muscle, near the bladder neck, while the catheter gave the sensation of passing into and through a roughened false passage, and then into a cavity from which bloody urine was drawn. As it seemed unwise to perform an external urethrotomy, with such an uncertain guide, the doctor determined upon a suprapubic cystotomy, to be followed, if necessary, by a retrograde catheterization, and then urethrotomy. The mucous membrane of the bladder was found highly congested and thickened, as a result of the cystitis, and upon examination of the internal orifice of the urethra this was found quite occluded by what to the finger felt like a semisolid roughened mass. This mass reached backward, and spreading out,

covered the base of the bladder, to which it was firmly adherent, and when removed, seemed like a partly solidified gauze wipe, covered with a deposit of urinary salts, and triangular in shape, the sides being 6 to 7 cm. in length, the anterior angle or point being twisted and pushed into the urethra (as one would do with a piece of gauze when trying to plug an opening), for a distance of about 1½ cm. But slight hemorrhages from the place of attachment occurred. The urethra was found patent and a full-sized sound passed. Drainage was ob-

tained both suprapubically and through the urethra. As there was considerable cystitis present, these drainages were both left *in situ* for some time, the suprapubic tube for two weeks (five days after which the wound closed), and the catheter for three weeks (irrigation having been kept up from two to five times in twenty-four hours). Subsequently the wound reopened, with considerable leakage, and this remained so for several weeks. A perineal drainage was done, but when the patient left the hospital there was still leakage. The exact nature of the mass was impossible to learn; macroscopically i

looked like a gauze wipe, though this was soon disproved both by no history of a previous operation, and by microscope. The diagnosis lay between an exfoliated mucous membrane, the results of the prolonged cystitis, and the remains of a blood clot. The pathological report said that "it was impossible to say whether it was the remains of a blood clot, from which the blood had been washed out, or whether it was originally tissue, as in one or two places it looked like necrotic tissue, but the appearance was not decisive."

Gangrenous Peri-urethral Abscess, of Diabetic Origin.—Dr. M. W. Ware reported this case. The patient was a man, sixty-two years old, who had called his family physician to attend him for chills and fever, which had existed for two weeks. When the physician saw him he excluded everything but malaria, taking into consideration everything that was possible, such as infection, sepsis, etc., examining carefully every portion of the man's body. At the end of two weeks the patient for the first time complained of pain in the perineum, where a swelling was found. This man appeared to be in perfect health and the only statement made concerning himself was that he had had diabetes for twenty years. Absolutely nothing further could be learned from him about the swelling and tenderness in the perineum. There was no redness over it. An examination per rectum revealed the swelling very close to the prostate. The prostate was in a condition consistent with a man of his age. He only got up once a night to urinate. Although he passed large quantities of urine, it was passed in a perfect stream. There was no discharge of blood or pus from the urethra. In fact, there was no clue whatever to the origin of the abscess other than diabetes. He had no temperature or pain and no fluctuation could be detected in the swelling. The mass was incised and a very large amount of pus and slough was evacuated from the perineum. The bulb was exposed and the urethra became visible and looked somewhat peculiar. It occurred to the doctor that if he packed the opening tightly to control the bleeding the patient might have difficulty in passing his urine. He was on the verge of cleansing the urethra preliminary to catheterization when suddenly there was a great escape of blood, and he then thought of the likelihood of a stricture. The catheter was introduced, but could not go beyond a certain point. He found that he had to deal with a gangrenous slough of the urethra. What prevented the escape of pus and blood into the urethra was the mucous membrane, which was intact up to the time of operation. He attempted to drain the bladder, but could not find the proximal portion of the bladder. Not one drop of urine came from the bladder, even when pressure was exerted. Of course, the only thing to do was to drain the bladder, and, therefore, he did a retrograde catheterization, making a suprapubic section. The operation was successful, although very protracted, lasting three hours. The patient lived ten days in fairly good condition, when signs of coma developed and he died. The wound never healed kindly. There was a primary gangrenous cellulitis in the vicinity of the urethra which would not perforate. The question of the propriety of doing a suprapubic section was dwelt upon by the speaker and he thought that if the patient had been left alone sufficient drainage would have occurred from below.

Dr. Pedersen agreed with Dr. Ware's own criticism, in thinking that the suprapubic cystotomy could have been avoided. The urine would have escaped through the perineal wound or could have been drained off through the perineal wound without producing any bad results. He had seen several cases of perineal abscess, sometimes surrounding the bulb of the urethra, sometimes situated to one or the other side of the midline, for which there was nothing to account, except the absorption of pyogenic germs through the skin or through the urethra. All of these abscesses had been very tense and had given very little sense of fluctuation. When incised the pus had spurted out with force.

Dr. Ware said that there was no fluctuation at all, but the abscess was very tense. He did not pass a sound in the beginning. He foresaw no indication for it, because the patient gave no symptoms referable to the bladder, except that he got up once a night. He believed that had he passed a sound at first a large amount of blood and pus would have escaped at once. When he opened the abscess in the perineum there occurred a large spurt of pus, which was followed by great relief; this pressure, he thought, must have torn this urethra, which allowed the escape of blood and pus. With regard to the origin of the abscess he said he was at a loss to account for it. When abscesses are found in diabetic and gangrenous cases, it was customary to fall back for an explanation upon the local element of arteriosclerosis and this certainly existed in this patient, who was sixty-two years old. The infection he thought possibly came from the rectum or uretnra. There was also to be considered the possibility of stone in the urethra which escaped with the pus, and blood when the abscess was opened, but this view is purely hypothetical.

Cases of Urethral Stricture and Their Management.—Dr. James Pedersen read this paper, and said that it comprised the report of seven cases, chosen to illustrate some of the phases and complications of urethral stricture, and to describe the management that seemed appropriate to each individual case. The term "management" was preferred to the term "treatment of stricture," because including all that was necessary to secure to the patient the best ultimate results. Case I was one of a small caliber stricture, complicated by an acute specific urethritis. The urethritis ran its course in five weeks under a hand injection of 1-30,000 bichloride and hot sitz-baths, followed later on by a mild astringent, without causing retention. Dilatation was not begun until two weeks later, and had reached a No. 20 F. when the patient disappeared from observation. Case II was one of irritable and somewhat resilient stricture, which yielded to careful, persistent, dilatation in spite of interruptions in the course, during the patient's absence abroad. The patient entered the hospital with retention of urine, which was relieved with filiform guide and tunnel catheter. A urethral chill followed the first three dilatations, and on one occasion spasmodic retention supervened. Thereafter, by the administration of quinine, irrigation of the urethra with 1-30,000 bichloride, and the use of sterile oil for the lubricant, a recurrence of the chills was prevented. Topical applications of protargol at first and later a silver nitrate solution (1-1,000) were used to overcome the irritability. A month before the end of the second year the patient was passing a No. 29 F. steel sound every third week without reaction and without other precaution than ordinary asepsis. This was discontinued six and a half months later, and now, at the end of a year, neither recontraction nor irritability had developed, and the caliber remained 29 F., as proven by a recent exploration.

Case III presented with a filiform stricture of long standing, deep within the penile urethra. Every course of dilatation that the patient had undertaken had produced epididymitis; consequently he had neglected himself. Once epididymitis had developed independently of any instrumentation. The urine was cloudy, faintly ammoniacal, and full of shreds. After five days of preparation, during which the patient used a hand in-

jection of 1-30,000 bichloride of mercury solution, drank freely of water, and took cystogen, dilatation was begun with a filiform and No. 12 F. tunnel catheter. By the utmost conservatism and the use of 1-3,000 silver nitrate solution instilled into the bladder and voided after each instrumentation, the caliber of the stricture had been increased to No. 24 F. at the end of the fifth month without producing epididymitis or in any way interfering with the patient's attention to an active business. Four months later, in the presence of concentrated urine, the result of errors in diet to which the patient was prone, and immediately after violent exercise and a slight traumatism to the testicle, epididymitis occurred eight days after instrumentation. This accident had occurred in all four times under Dr. Pedersen's observation; twice under conditions similar to the above, and twice after careful attempts to increase the caliber to No. 26 F. The condition of the bladder and the urine remained good, and the patient's general health was now perfect. Treatment in this case was now centered upon the granular condition of the deep urethra.

Case IV applied for the relief of a urinary fistule that opened in the perineoscrotal angle; it leaked urine continuously and allowed a large quantity to escape during every urination. This condition was consequent upon a complete rupture of the urethra sustained one year before. A competent surgeon had operated to relieve the extravasation, which had become extreme and subsequently had reunited the torn urethra. The after-treatment had been interrupted, and the patient had been left in the above described condition. His general health and spirits had become greatly impaired. Examination disclosed a tortuous, filiform stricture in the midpenile urethra. Gradual dilatation with filiform and tunnel instruments and topical treatment of the urethral mucous membrane with silver nitrate solutions closed the fistule on the fifteenth day, when the caliber had reached No. 20 F. Thereafter, as the dilatation progressed at intervals of from one to two weeks, the sinus was alternately open and closed, but at most it allowed only a few drops to escape during urination (the continuous leaking having permanently ceased), until, in the course of the twenty-first week, it closed permanently. The patient now was taught to pass his own sound and the topical treatment of the urethral mucous membrane was continued. Long before this he had recovered his health and had resumed active business. When last seen, a year ago, he was passing a No. 28 F. easily once a week, and had been given instructions to report for inspection, that the frequency with which he should pass the sound could be diminished if possible.

Case V was one of recontraction to a filiform stricture following a neglected urethrotomy performed twelve years before. The smallest tunnel instrument could not be guided through the stricture. The patient being a drinking man, was not able to cooperate properly, and after two attempts to dilate the stricture beyond the risk of retention, an external urethrotomy was performed in the usual way. The patient left the hospital on the thirteenth day and the usual after-treatment was begun.

Case VI was taken as typical of stricture of large caliber, with secondary posterior urethritis and urethrocystitis due to an antecedent urethritis, the irritation of the stricture itself, the excessive use of tobacco and coffee, lithuria, and the practice of withdrawal, in which the patient had indulged three times a week for the three preceding years. The patient had received various forms of treatment with only very temporary benefit. He had begun to use morphine suppositories. The symptoms were so suggestive of vesical calculus that after excluding acute prostatitis, the bladder was searched, but with negative result. Tuberculosis was next excluded. Under rest in bed, bland diet, free diuresis, cystogen and very gentle irrigation of the bladder from the meatus, any distention of the bladder being avoided, he began to improve at once. So soon as the acute symptoms had abated an examination was made that disclosed the stricture of large caliber. This was dilated to a No. 26 F., and the urethral mucous membrane was treated with the usual topical applications of protargol solutions first and silver nitrate solutions later; four times at weekly intervals and again at the end of two weeks. He returned home entirely free from all urethral irritability.

Case VII was one with a series of strictures of about 14 F. in the course of the penile urethra, and a foul scrotal abscess of four months' standing due to extravasation. Through the sinus leading to the abscess a large volume of urine escaped with each urination. The patient was poorly nourished, and in bad general condition, being slightly septic and uremic. After three days of the usual preparatory treatment an external urethrotomy was performed in the usual way, the abscess sinus dissected out, and the abscess thoroughly curetted and drained. A catheter-splint was left in the penile urethra until the fifth day. Perineal drainage was maintained until the tenth day. Owing to a misunderstanding a sound was thereafter passed somewhat too frequently until the seventeenth day. It was then discontinued; but irrigation of the bladder with boric solution once daily was begun to correct the cystitis. Through an error the bladder was filled to its capacity at each irrigation. Thereupon the patient developed an irregular temperature, ranging from 99° to 104° F. The bladder irrigation was discontinued at once. Under free diuresis, stimulants, the urinary antiseptics and creosote, the fever ran its course in about three weeks. The sinus and wound in the scrotum healed permanently without interruption. The patient is now in excellent health, and his urethra has the caliber of a No. 24 F. The paper closed with a summary of certain details in the technic, namely: irrigation of the penile urethra; the choice of instruments; the treatment of the bladder; the topical treatment of the urethral mucous membrane, and the regulation of the patient's use of a sound when necessary.

Dr. Albert A. Berg said he was very much interested in the relation of the cases by Dr. Pedersen, and especially in the one of ruptured urethra, and he wished to know the condition of the tissues of the perineum at the time of operation, when extravasation existed, and whether the parts were gangrenous or not. He asked this question in order to bring forward the advisability of attempting to get primary union of the divided ends of the urethra and to consider the method by which such union should be made. If the tissues were gangrenous primary union was out of the question. The result obtained in such cases from passing a catheter through the urethra into the bladder to permit the parts of the severed urethra to regenerate as proposed by Guyon, was so good that it was a question whether we should complicate such a possibility by attempting to get primary union with sutures. Where we wished to avoid a prolonged after-treatment such sutures might be made by an end-to-end anastomosis. He had recently resected the penile urethra in a boy six years old, for primary stricture and cicatricial stenosis of the canal, and he made an anastomosis by Maunsell's method. The final result was good and no stenosis followed the operation. He believed that Guyon's method of passing the catheter into the bladder from the penile portion fulfilled every purpose.

Dr. G. M. Muren, of Brooklyn, took exception to the use of an 18 F. sound by the patient in the first case re-

lated by Dr. Pedersen. He did not believe it was proper to allow the patient to pass an urethral instrument on himself unless the sound was a large one, and used after the surgeon had dilated the stricture. Students were taught differently. In Dr. Pedersen's fourth case the bladder was entered with a small instrument and he believed that if one could get into the bladder even with a filiform guide urethrotomy was not indicated, except in a very small proportion of cases when of traumatic origin. He thought that if the doctor had persisted with the filiform and tunnel sound, he might have avoided operation. Almost all urethral strictures could be treated by dilatation unless of traumatic origin. The Maisonneuve, the smallest urethrotome, equaled an 8 F. sound, and if an 8 F. could be passed there was very rarely any indication of urethrotomy.

Dr. Walter B. Brouner said that the conservative manner of treating his cases was highly instructive. The more cases one saw and the more operating on such that one did made one the more conservative, and good results would be obtained if one waited long enough.

Dr. Howard Lilienthal said that a great many strictures were now dilated which would have been cut a few years ago. When patients show signs of sepsis after every manipulation about the urethra, then he believed every manipulation became practically an operation. The case reported undoubtedly had to be cut and perineal section was the operation to be preferred. He recollected cases which came under his notice, fortunately not his own, in which fatal sepsis occurred following catheterization. He had had two cases; one of these died of sepsis on account of an urethral instrument being passed by a very competent man. Dr. Lilienthal had the misfortune to have one case in which he did an internal urethrotomy one and a half inches back of the meatus in a very susceptible individual, who had septic symptoms after each instrumentation. He should not have performed this operation without perineal section in this particular individual. At post-mortem there was found a general staphylococcus infection with hemorrhages in the brain and serous cavities. Before doing internal urethrotomy the patient was for three days carefully prepared for operation, washing out the urethra with boric acid solutions, etc., and every possible precaution taken, but still the patient died of sepsis. Every time a sound, or soft instrument was passed the patient had a decided chill, and each time it was thought he would die. In ordinary cases he thought we should persist in dilatation. He asked Dr. Pedersen how long the third case was kept in bed with each attack of epididymitis.

Dr. James Pedersen said that the patient was kept in bed from two to four or five days. The patient had had several attacks of epididymitis before coming under treatment. Within the past year, after being free from them for nine months, he seemed to become more or less used to them, and the testicle was strapped and supported and the man was then able to go about his business.

Dr. Pedersen could not say whether actual gangrene had occurred in the case of ruptured urethra. The patient had not been informed as to such details and he inferred not. It might be assumed, he thought, that the surgeon postponed the suture operation because the tissues were so infiltrated (the extravasation having been in existence forty-eight hours) that to find the ends of the urethra would have been very difficult. Regarding the patient who ran a protracted temperature, he ascribed it to a pyelitis or to some chronic focus in the kidneys reawakened by the back pressure exerted when the bladder was overdistended with the irrigating fluid contrary to orders. The patient was fifty-nine years old and had had a strictured urethra for many years; therefore, the ureters must have become dilated and the kidneys more or less affected. He did not think the temperature due to the instrumentation alone, as that had been successfully performed for several days without exciting any reaction. Regarding the use of sounds of small caliber (less than a No. 20 F.) by a patient, he agreed with the speaker, who offered the criticism, but believed that on occasions an exception could be made to the rule he himself followed, not to allow a patient to pass a smaller sound than 24 F. He believed the case in question justified an exception, as the patient was familiar with the peculiarities of his own urethra, and as the passage of the sound was performed in the office under his supervision. He could not agree with the same speaker that the proper management for all strictures was dilatation. He took the position that every attempt at dilatation should be made before resorting to urethrotomy, and from his experience he could say that by far the larger percentage of strictures would yield to persistent, careful, gradual dilatation, as he thought he had demonstrated in the cases reported; but he believed that there were a few cases in which urethrotomy was the better management. Regarding sepsis and the wisdom of performing urethrotomy instead of dilatation in cases where sepsis had occurred, he believed that such an accident as Dr. Lilienthal had related would occur in the practice of every genito-urinary surgeon. He himself had had the experience twice, the first case was that of a large, robust man on whom, after suitable preparation, he had performed an internal urethrotomy for a stricture situated three inches from the meatus. Eight hours after the operation the patient died. The second case was that of an old man living at a distance from the city, whom he saw in consultation. The symptoms were those of vesical calculus. Catheterism under the usual precautions had been performed a few times in the course of the preparatory treatment. Suddenly the patient developed a severe chill and died at the end of half an hour. Before approaching such a case he believes it necessary to caution the family that the patient had reached a critical period in his life and that considerable risk attended such a simple operation as catheterism under those conditions. He had never had any ill effects from the use of iodoform oil. Nevertheless he had already abandoned it for the use of plain sterile sweet almond oil, which was fully as useful. He believed that plugging the orifice of the fistule in the case of traumatic rupture in order to retain a solution of eucain would not have accomplished the result, as at the time when the local anesthesia was most needed it would have flowed from the urethra back into the bladder. The patient who had suffered recurring attacks of epididymitis had remained in bed from two to five days with each attack. By strapping the testicle the patient had been able to get about very soon after the development of a mild epididymitis. He pointed out that no epididymitis had occurred during the first nine months of treatment.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, held Thursday, October 1, 1903.

The President, John M. Fisher, M.D., in the Chair.

Gauze-bearing Tape, and the Gravity Pad, in Pelvic and Abdominal Surgery.—Dr. John M. Fisher read this paper. The one, it is claimed obviates the annoyance of a miscount in the number of gauze pads used for isolating and exposing the field of operation,

and positively eliminates the danger of the loss of any pads within the abdominal cavity, at the same time minimizing the possibility of losing unsecured pads for rapid sponging, while the other supplements and enhances the advantages of the Trendelenburg posture. The gauze-bearing tape consists of a piece of white tape about a half inch in width and of variable length (three or four feet) armed at one end with a long blunt-pointed needle or bodkin. The gravity pad is nothing more than a large gauze pad, concealed within its folds and fastened to the center of which is a lead plate two by three inches and weighing a half pound. Instead of a single piece of lead smaller plates of the metal may be held in quilted squares of the pad or at indifferent points. The practical utility of the tape was first demonstrated by Dr. Fisher at St. Joseph's Hospital, Philadelphia, on July 27, 1903, in an operation for pelvic disease requiring a number of gauze pads to hold the intestines at a proper level and expose the field of operation. One end of a long piece of gauze was introduced into the abdomen while the nurse quickly, and without any loss of time to the operator, perforated the other extremity with the needle and tape, securing its edge to the distal end of the latter with a turnover tie. After the entire pad had been packed into the cavity with the free portion of the tape trailing from the abdominal opening, other pads were strung on the tape in a like manner but without the necessity of securing them with a knot—the first and successive pads acting as points of fixation for those that followed. No account was taken of the pads thus introduced, nor was this necessary, for the reason that, after a sufficient number were in use to answer the purpose indicated, the removal of same upon the completion of the operation, simply depended upon the withdrawal of the tape to which all were attached. On the following day the same device was used with entire satisfaction in an operation for suppurative appendicitis; while the combined advantages of the gravity pad and the tape were first employed in an unusually trying case of suppurative disease of the uterine adnexa. In operating upon the latter patient it was shown that weight properly distributed is of more importance than bulk in holding the intestines at a proper level. Without the gravity pad three times the quantity of gauze would not have given the same satisfactory result in isolating and exposing the pelvic contents. He contends that by the use of this pad the certainty not alone of confining the intestines to the upper abdominal cavity, but that the maintenance of a more or less immovable wall, against which gauze may be packed to isolate the field of operation and protect the healthy peritoneum from contact with infecting materials, seems to be assured. The gauze-bearing tape was employed in several other abdominal operations by Dr. Fisher with such uniform satisfaction that he feels inclined to continue its use until a more certain method, or a simpler device is presented to safeguard the surgeon against the loss of a sponge within the abdominal cavity—an accident that has befallen some of the most experienced, and very many of the most careful and eminently painstaking operators of our day.

Report of a Case of Rupture of the Parturient Uterus in which Hysterectomy was Followed by Recovery.—This case was reported by Dr. Francis T. Stewart. The patient, a multipara, aged thirty-eight years, had never experienced any unusual difficulty during previous labors. During the last labor she had vigorous uterine contractions up to the seventeenth hour, when the pains suddenly ceased with an enormous hemorrhage from the vagina. Three hours later a dead child was delivered by podalic version. In removing the placenta, which came away spontaneously a large portion of the omentum was found in the vagina. The patient was exsanguinated and very much shocked. Seven hours after the rupture a total abdominal hysterectomy was performed. The laceration of the uterus extended along the left lateral wall from near the fundus down to and into the vagina. The uterus contained a few scattered fibroids and was abnormally friable. The patient made an uninterrupted recovery.

Structures Taking Part in Menstruation.—This paper was read by Dr. E. E. Montgomery, in which he discussed the occurrence of menstruation, the phenomena of increased arterial tension, the tendency of weak vessels to rupture in different portions of the body, and where the hemorrhage following was sufficient to reduce the blood tension, that such hemorrhage would take the place of menstruation, and be known as vicarious menstruation. He discussed the various theories as to the cause of its periodical occurrence, referred particularly to the investigations of Fraenkel which disclosed the glandular character of the corpus luteum, and the probability that its secretion produced an influence upon the blood and nervous system sufficient to induce the recurrence of menstruation where fecundation had not taken place, and to assist in the retention and nutrition of the ovum when fecundated. He asserted that menstruation did not take place in the absence of the ovaries; that the menstrual flow occurred from the Fallopian tube as well as from the uterine mucous membrane. This was evident in the anatomical structure of the tube from the fact that blood was found in the tube in cases which have undergone operation during menstruation; that patients in whom fistulous tracts communicate with the tube have a bloody discharge during the menstrual flow. This view, however, has been combated and the occurrence of hydrosalpinx presented as evidence against it, the fluid here being perfectly clear, which, it is asserted, indicates that menstruation does not take place into the tube, but such cases are examples of diseased tubes in which the inflammatory changes have rendered the vessels more resistant and less likely to rupture. In his opinion many cases of hematosalpinx are the result of the retention of menstrual products.

Tubal Menstruation.—Dr. F. Brooke Bland read this paper by invitation, and said that this case was one of exceeding interest, not alone from the fact of its rarity and from the study of the part played by the tubal mucous membrane in the process of menstruation, but also the lesson it taught in the diagnosis of postoperative fistulæ following abdominal section. Ten months before presenting herself for examination the patient was operated upon for a large intrapelvic (probably broad ligament) abscess. She apparently made a complete recovery from this condition. Shortly after leaving the hospital, however, a small abdominal sinus developed almost simultaneously with the establishment of the succeeding menstrual flow, in the line of the old abdominal incision. On coming under the writer's observation ten months subsequent to her first operation, a small sinus was discovered in the lower half of the old abdominal scar. This readily admitted to a considerable depth an exploring probe. The material discharged from this opening was at times comparatively nil, but during, or, indeed, a day preceding the menstrual period, the discharge increased in quantity, became bloody and assumed all the characteristics of menstrual fluid. The patient was operated upon, and on entering the abdominal cavity, the fimbriated end of the right Fallopian tube was found adherent to the old abdominal cicatrix, and thus the behavior of the abnormal canal, particularly during the menstrual period, was explained. The author is persuaded from the phenomena manifested by this patient that during menstruation the tubal mucosa undergoes changes similar to the uterine mucosa,

though, perhaps, to a somewhat less degree, and thus confirms the observations of some of our most eminent investigators. He is further persuaded that if the function of menstruation is to prepare the endometrium for the implantation and development of the ovum, that the same changes, therefore, are essential to the implantation and development of a tubal or extra-uterine ovum or pregnancy. The practical deductions to be drawn from this case, according to the writer, are (1) that the tubal mucous membrane is an active participant in the process of menstruation; (2) that factors other than the presence of foreign bodies and infected ligatures must be considered in the causation of postoperative abdominal fistulæ; (3) that in the future consideration of the etiology of tubal gestation, the part played by the tubal mucosa during menstruation must be a factor for study. From a perusal of the literature he found but four similar cases recorded, one each by Hoffmeier, Lansdsberg, Serrillon and Thompson. For the privilege of reporting this case the writer acknowledges his gratefulness to Dr. E. E. Montgomery.

Dr. E. E. Montgomery, in the discussion, said that the device which Dr. Fisher had exhibited was certainly worthy of consideration and employment. He knew of nothing that gave him greater anxiety in the performance of an operation than the fear of leaving a piece of gauze in the abdominal cavity. He has not had the privilege of having this procedure introduced to him in St. Joseph's Hospital, and he congratulated Dr. Fisher upon having been so fortunate as to know of this very simple device, which can be employed with such ease, and which makes sure the removal of all the gauze from the abdomen.

Dr. A. J. Downes remarked that in the consideration of Dr. Stewart's paper the question occurred to him whether under similar circumstances the average surgeon would be justified in removing the uterus. Theoretically, it was altogether better to do this, because the inside of the uterus had the possibility of infection, in that the omentum had already been exposed to the air. At the same time, there are few surgeons, who, with a patient as low as this one, could have removed the uterus in twenty minutes. Under the circumstances, the average man would probably be doing better for the patient if he sewed up the rents, and pulled the omentum out through the vagina, after completing a good peritoneal toilet.

Dr. E. E. Montgomery said that the question has been raised regarding the advisability of doing hysterectomy in this case, and in similar ones. He is inclined to believe, from the description which Dr. Foltz gave of his case, of the patient's environment, etc., that hysterectomy was her salvation. Had anything less than that been done the patient would certainly have died from infection. By removal of the uterus, however, the infected structures were removed and the patient saved. He feels that the fact that this operation was done so skilfully and so quickly was due to the opportunities that Dr. Stewart had in his early career, and he is very proud of him.

Dr. Stewart, in closing the discussion, said that the pregnant uterus is large, easily held, and can be gotten out with less time and trouble than a large rent could be sewed. With the uterus as large as it is in pregnancy, with clots of blood and remains of placenta tissue and shreds, which are good culture media, he should think to remove all and leave the abdominal cavity clean, would be the safest course.

Dr. F. H. Maier said he wanted to congratulate Dr. Bland upon his paper, and upon the rare case which he found. Those cases which have been reported of blood coming from the end of the tubes, either through the abdomen or through the vagina, do not prove that the tubal mucosa takes any active bleeding part in the performance of menstruation. It has been known for a long time that hemorrhage from the mucous membrane of the tube does occur during menstruation; but these cases have invariably been ones in which either the tubes or the uterus have been pathologically altered, the alteration usually being inflammatory, a condition in which the structures are quite different from the normal. We know that in the one we have increased number of vessels with hyperemia, so that when the extra flux of menstruation occurs, the vessels are more liable to rupture, with consequent pouring out of blood into the tubes. The mere fact that the profession has so few hematosalpinges as compared with the large number of hydro- and pyosalpinges, is to his mind, evidence enough that it does not have, properly speaking, tubal menstruation. Fritsch and other men, who have removed uteri during menstruation, and who have examined the tubes carefully macroscopically and microscopically, demonstrated that at the most there may be increased secretion, and in some cases, a small number of red cells. There is also a weakness in the case reported by Dr. Bland, in so far that a sister died of uncontrollable epistaxis. Take the history of abnormal bleeding in the patient, together with a bleeder in the family, and the changes in the tubes, and you have ideal pathological conditions that would conduce to hemorrhage from the tubes. Up to the present time, there have been very few cases of tubal menstruation reported. In the case of Chapin-Minard, in which he actually saw blood coming from the uterine end of the tube in a case of inverted uterus, another pathological condition of the tube was had. In a case reported by Wendler, in which hysterectomy was done and the uterine end of the tube caught in the vaginal opening and allowed to remain, there occurred each month, simply an increase of mucous discharge without any hemorrhage. Up to the present time there have been extremely few cases in which blood has been found coming directly from the tube, and these cases undoubtedly have been ones in which there were pathological changes. In most of the cases reported by Bohn the tubes were removed for disease, for a myomatous condition of the uterus or for ovarian conditions.

Dr. Francis T. Stewart has operated upon two cases of ectopic pregnancy during the period of lactation. In one case in which the tube had ruptured, menstruation had not occurred between the time of labor and the time of rupture, eleven and a half months, so that in this case ovulation was not accompanied by menstruation. In the second case rupture occurred eight months after labor. There had been some bleeding from the uterus, which was probably due to the ectopic pregnancy rather than to menstruation. He simply mentions these two cases as bearing upon the relation of ovulation to menstruation.

Dr. Barnes would not cast any doubt upon the apparently strong evidence this case gives as to tubal menstruation, but asked a question simply to clear up a doubt in his own mind. Dr. Bland has stated that the probe passed readily through the old wound, probably into the uterus. It seemed to him in that case it was not improbable that the flow of blood may have been regurgitant blood from the uterus at the time of menstruation. That fact raised a grave doubt in his mind as to the validity of the proof that this case seems to give of tubal menstruation.

Dr. Montgomery, in closing the discussion, said that in regard to the objections which Dr. Maier presented to the possibility of tubal menstruation, and the fact that these cases were inflammatory, and that the latter was the cause of the hemorrhagic discharge from the tube, it is true that most of the cases coming under observation are diseased; but he is inclined to believe

that the inflammation of the tube associated with more or less hyperplasia in the majority of cases one sees the tendency would lead to a decrease of hemorrhage under the influence of blood pressure rather than increase. This is the reason hydrosalpinx or pyosalpinx are not found in the ordinary fluid discolored by blood. It is true that the tube cannot take an active part in the process of menstruation. When one comes to consider menstruation one knows that the discharge of blood is due to increased blood tension, so that the vessels rupture in that portion of the body in which they are the weakest. As the mucous membrane of the tube is similar in character to that of the uterus, except that it doesn't have the glandular structure, it is reasonable to suppose that in a healthy tube we would be likely to have rupture of the capillaries in the tube as in the uterine cavity. The profession well knows that the cervix doesn't take part in menstruation.

Dr. Bland, in closing, said in reply to Dr. Maier's objections relative to the tube undergoing changes when associated with ovarian neoplasms or fibroid tumors of the uterus, desired to state that he has found but very few tubes manifesting any gross change when removed with pathologically altered uteri or ovaries. They are, however, sometimes found. In regard to the question of regurgitation, this tube, in his judgment, was drawn to a higher level than it normally maintains, and, therefore, it would render regurgitation extremely difficult. Moreover, with the patient in the erect posture and the larger opening below, it is perfectly natural to suppose that the uterine menstrual flow would seek the most easy means of exit. He does not think this was an instance of backward regurgitation. He has also been privileged to inspect the internal genital organs of the woman during menstruation, but never examined them with a view to ascertain their true position in the menstrual process.

Exhibition of Specimens.—By Dr. A. J. Downes.—The patient was a woman, forty-eight years of age, with a history of bleeding for the last three years. Rapid abdominal examination revealed the presence of a very large mass. He operated upon her at once. He had not examined her per vaginam until just before the operation, while she was on the table. He thought she had a fibroid, and only then found that the body was fairly cystic. He still thought it was the uterus entirely, so he purse-stringed the cervix with a view of doing a complete hysterectomy. Through a very thin abdominal wall he found the cyst multilocular. It was removed by his electrothermic clamp. The uterus he found large and soft. He removed it with his electrothermic angiotribe, including the cervix. An explanation of the bleeding was found in the presence of two polypi within the uterus. There is a suspicious area, an excoriated surface that will require an examination for malignancy. This is the thirty-second hysterectomy he had done with his angiotribe, and he has practically done 12 others with other surgeons. This was the third hysterectomy to-day. He assisted another surgeon in the removal of two uteri, one a case of cancer, and one an exsanguinated patient who had been bleeding constantly for a number of years. The uterus of this bloodless patient was removed quickly by the surgeon with practically no loss of blood. He had about eight doctors present at his own operation, and no one thought there was a teaspoonful of blood lost. Almost anything can be done with sterile ligatures; the more he uses this method of performing hemostasis within the abdomen the more certain is he that it is far superior to ligatures. He can work more quickly to-day with it than when he was using ligatures two years ago. He has not used a ligature in any place for two years. He can report cases in the hands of other surgeons, such as removal of the shoulder-joint, with hemostasis of the axillary artery, and cases requiring hemostasis of the femoral artery. In hysterectomies the broad ligaments are hemostased and remain closed. A white ribbon is seen traveling down the lateral walls of the pelvis, and with good technic one need never suture the peritoneum at the lateral walls of the pelvis. The only sutures he uses are one or two at the cervix. The results seems to him to be better, and this is the opinion of other men using the instrument. There is less abdominal pain following hysterectomy with the use of this instrument than when ligatures are used. The Fallopian tube is always non-adherent after this method.

Exhibition of Three Specimens of Gonorrheal Pus Tubes.—Dr. George Erety Shoemaker exhibited three specimens of gonorrheal pus tubes. In each instance the patient made a good recovery. No drainage was employed. In one case the diagnosis of extra-uterine pregnancy could readily have been made from the symptoms of delayed period followed by very severe abdominal pain in paroxysms and bleeding from an empty uterus; while the lateral pelvic masses and blue discoloration of the vagina were suggestive.

SPECIAL ARTICLE.

THE HOME IN ITS RELATION TO THE TUBERCULOSIS PROBLEM.*

BY WILLIAM OSLER, M.D.,

OF BALTIMORE, MD.,

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY.

I.

In its most important aspects the problem of tuberculosis is a home problem. In an immense proportion of all cases the scene of the drama is the home; on its stage the acts are played, whether to the happy issue of a recovery, or to the dark ending of a tragedy, so commonplace as to have dulled our appreciation of its magnitude. In more than 400 homes of this country there are lamentations and woe to-night: husbands for their wives, wives for their husbands, parents for their children, children for their parents. A mere repetition of yesterday's calamities! and if the ears of your hearts are opened you can hear, as I speak, the beating of the wings of the angels of death hastening to the 400, appointed for to-morrow. That this appalling sacrifice of life is in large part unnecessary, that it can be diminished, that there is hope even for the poor consumptive—this represents a revulsion of feeling from an attitude of oriental fatalism which is a triumph of modern medicine. Our French brethren have made the present position of the question possible. Laennec, the father of modern clinical medicine, gave us the pathology of the disease—and much more. While Galen, Frascatorius, Morton and others believed strongly in the contagiousness of phthisis, it remained for Villemin to demonstrate its infectiveness by a series of brilliant experiments which made Koch's work inevitable; while to Verneuil, Chauveau, Nocard, Brouardel and others we owe the initiation of those local and international congresses which have done so much to rend the veil of familiarity, and to educate the public and the profession to a point at which scientific knowledge has become effective. It seems a law that all great truths have to pass through a definite evolution before they reach a stage of practical utility. First the pioneers, seeing as through a glass darkly groped blindly for the truth, but worked so effectually that by the seventh decade of the nineteenth century we had a clear pathology of tuberculosis and an accurate symptomatology; while in each generation a man had not been wanting, who, like Sydenham, or George Bodington, appreciated the essentials of treatment, as we recognize them to-day. Then Villemin and Koch demonstrated the truth of the infectivity of the disease and the presence of a specific germ. Watchers on the towers, like the late Austin Flint, a lifelong student of the disease, welcomed the announcement as the much-wished-for fulfilment of a prophecy; but, as Plato shrewdly remarks, we are not all awake when the dawn appears, and many in this audience, like myself, had to see the truth grow to acceptance with the generation in which it was announced. It is a horrible thought, but very true, that we reach a stage in life, some earlier, some later, in which a new truth, a perfectly obvious truth, cannot be accepted; and the work of Villemin and of Koch fared no whit better with the seniles and the pre-seniles of the seventh and eighth decades of the last century than did Harvey's immortal discovery in his day, or for the matter of that, did Lister's great work. And now we are in the third or final stage, in which the truth is becoming an effective weapon in the hands of the profession and of the public. The present crusade against tuberculosis, which is destined to achieve results we little dream of, has three specific objects; first, educational—the instruction of the profession and the instruction of the people; second, preventive—the promotion of measures which will check the progress of the disease in the community; third, curative—the study of methods by which the progress of the disease in individuals may be arrested or healed. The three are of equal importance, and the first and the second closely related and interdependent. The educational aspects of the problem are fundamental. Nothing can be done without the intelligent cooperation of the general practitioners and of the community, and it is a wise action on the part of the Phipps Institute to take up actively this part of the work, and to spread a sound knowledge by lecture courses and by publications. It is not too much to say that could we get on the part of the doctors throughout the country an early recognition of the cases, with a practical conviction of the necessity of certain urgent and obvious measures, and on the part of the public attention to hygienic laws of the most elementary sort—could we in this way get the truth we know into the stage of practical efficiency, the problem would be in sight of solution.

Of late years there have been done in this country three pieces of work relating to tuberculosis of the first rank—that of Trudeau in the Adirondacks, enforcing on our minds the importance of the sanitarium treatment of early cases; that of Biggs and his associates in the New York Board of Health in demonstrating how much can be done by an efficient organization; and, thirdly, the work of Lawrence F. Flick, the Director of the Phipps Institute, in demonstrating by a long and laborious research the dangers of the house

* A lecture delivered under the auspices of the Phipps Institute, Philadelphia, Dec 3, 1903.

in the propagation of the disease. In casting about for a subject it seemed to me most appropriate to discuss those aspects of the problem which concern the home in its relations to the disease, since after all the battlefield of tuberculosis is not in the hospitals or in the sanitaria, but in the homes, where practically the disease is born and bred.

II.

The germ of tuberculosis is ubiquitous; few reach maturity without infection; none reach old age without a focus somewhere. This is no new opinion. Gideon Harvey, in his *Morbus Anglicus* (1672, 2d. Ed.), says: "It's a great chance we find, to arrive to one's grave in this English climate, without a smack of a consumption, Death's direct door to most hard students, divines, physicians, philosophers, deep lovers, zealots in religion," which is the English equivalent of the German popular saying, "Jedermann hat am Ende ein bischen Tuberculose." This may seem an exaggerated statement, but the records of Naegeli demonstrate its truth. After all, it is only from the post-mortem table that we can get a true statement of the frequency of tuberculosis in the community. It has long been known that a very considerable percentage of persons not dying from consumption have the lesions of tuberculosis. The records have ranged in different series from 7.5 per cent. (Osler), to 38.8 per cent. (Harris). But these studies were not made directly with a view of determining the presence of tuberculosis. They were the ordinary, everyday observations of the post-mortem room. The only series which we have dealing with this question in a satisfactory way is the study of 500 post mortems in Prof. Ribbert's Institute in Zurich, by Naegeli. It is to be borne in mind that in his work special examination was made of every organ of the body, sections were made of all parts with the greatest care, and the individual lymph glands particularly inspected. Tuberculous lesions were found in 97 per cent. of the bodies of adults.* He gives a very interesting curve showing the incidence at different ages. Up to the fifteenth year there was only 50 per cent., then there was a sudden rise in the eighteenth year to 96 per cent., with a slow rise, so that by the fortieth year a tuberculous focus was found in everybody. This careful research demonstrates the extraordinary susceptibility in man to tuberculous infection, and an equally extraordinary degree of resistance. In the tuberculin experiments of Franz on healthy Austrian soldiers a reaction was shown in over 60 per cent., so that we must accept the conclusion that tuberculous infection, latent tuberculosis, is much more extensive than is the manifest disease.

One interesting point is that we are never left long in peaceful possession of a satisfactory belief about the modes of infection in tuberculosis. No sooner had the pool got quiet and we had settled into a comfortable conviction of the unity of human and bovine tuberculosis, than Koch stepped in and troubled the waters with his views on their dual nature; and now, just as the commotion was subsiding, von Behring stirs the waters by referring all tuberculosis to the milk-jug. But none of these investigations have diminished the importance of the home as the chief source of infection, the place in which the conditions favoring contamination are most common, particularly among the poor. Nor do I think that we can give up the view of aerial convection and of primary inhalation infection in a large proportion of the cases. Figures are, of course, tricky playthings, but it does seem that the overwhelming evidence of the prevalence of bronchial and pulmonary tuberculosis in children is in favor of the older views. After all, how rare is intestinal tuberculosis as a primary lesion, and if, as von Behring supposes, there is a special vulnerability of the bowels in childhood, we should expect a much larger number of cases. It is quite possible, as he has shown, and as Ravenel has demonstrated, that the bronchial and cervical lymph glands may be the first attacked in an animal infected through the intestines; yet the incidence in childhood of respiratory disease is so large, and the incidence of intestinal lesions is so small, that it counts strongly against von Behring's new views. In fact, primary intestinal tuberculosis is extraordinarily rare. Koch states that there have only been ten cases in ten years at the Charité Hospital, Berlin, and of 3,104 instances of tuberculosis in children there were, according to Biedert, only 16 cases, while in adults primary intestinal tuberculosis occurred in but one instance in 1,000 autopsies at the Munich Pathological Institute. In this country the studies of Bovaird in New York and of Hand in Philadelphia speak strongly in favor of air-borne infection in the large majority of cases in children. There is a special liability of the milk to become contaminated by the dust in uncleanly streets and in dirty houses, and upon this mode of infection von Behring lays great stress, and in infancy, either in this way or from the milk of tuberculous cows, he thinks the majority of persons become infected. Apparently he does not adopt Baumgarten's view of the latency of the germ itself, but of the latency of small foci of disease acquired in childhood, which only develop into active tuberculosis under favorable circumstances. It may be well to quote his own words in this connection, as his views are of importance: "I am well acquainted with the statistical arguments based on the higher returns of infection and mortality from consumption amongst attendants on the sick residents in houses occupied by people known to be phthisical, and inmates of prisons, which are intended to demonstrate the origin of pulmonary phthisis from the inhalation of particles of dust, or moisture containing tubercle bacilli. But in view of the extensive dissemination of tuberculosis above described amongst the human race, there is ample justifi-

* Virchow's Archiv, 1900, Bd. CLX, page 426.

cation for the objection that in cases of this kind, where persons succumb to pulmonary phthisis, tuberculous foci pre-exist in their lungs, and that these pulmonary lesions already present developed into active consumption, owing to the adoption by those persons of a mode of life favoring tuberculosis." (*British Medical Journal*, Translation Oct. 17, 1903.)

We need a systematic inspection, according to Naegeli's method, of the bodies of children dead of acute diseases, so as to get, if possible, the true incidence of infection in them. Councilman and others have shown how frequently tuberculosis is present in the bodies of young children dead of diphtheria, but the statistics at our disposal certainly do not bear out this view of von Behring, which would lead us to suppose that infection was largely a matter of childhood. Naegeli's figures on this point are interesting, though he only had 88 autopsies on children. Still his results are of value, as the inspections were made with such very special care. Of these 88 children there were only 15 with tuberculous lesions. In 10 of these the tuberculosis ran a fatal course; in 4 there were advanced lesions which did not cause death, and in only 1 was there a definitely healed lesion.

Sown broadcast as they are in our modern life, it is evident that few people reach maturity without harboring the seeds of tuberculosis. That we do not all die of the disease is owing to the resistance of the tissues, in other words, to an unfavorable, *i.e.*, the rocky soil on which the seeds have fallen. The parable of the sower sets forth in an admirable way the story of the disease. Since I used it in 1892, the illustration has become hackneyed, but in a semi-popular lecture I may be permitted to employ it again. The seed that falls by the wayside are the bacilli that reach our great highways, the air passages and intestines, in which they are picked up by the phagocytes, representing the birds of the air, or they are trodden under foot by the swarms of contending organisms. The seed that falls on stony places is that which reaches the lymph-nodes of the bronchi and mesentery, and though it springs up and flourishes for a while, there is no depth of earth, and, lacking moisture, it withers away into cretaceous healing. And that which falls among thorns represents the bacilli which effect a lodgment in the lungs, the kidneys or elsewhere, where they thrive and grow and produce extensive changes, but the thorns—the equivalent of the cares of this world and the deceitfulness of riches, in the parable—grow up also, and in the form of delimiting inflammatory processes and of contracting fibrosis, choke the seed, and recovery ultimately takes place. But falling on good ground, the seed springs up, increases and brings forth fruit some thirty, some sixty and some a hundredfold, which may be taken to represent the cases of chronic, subacute and acute tuberculosis. We are beginning to appreciate that the care of the soil is quite as important as the care of the seed. We cannot repeat Trudeau's remarkable environment experiment in our cities, but we learn a practical lesson of the influence of fresh air, open spaces and sunlight upon infected individuals. Much has already been done in this direction, and the reduction of the mortality from tuberculosis which has been going on for the past twenty-five years has been in great part due to improved sanitation. We have only made a beginning, but to know the enemy in this case, to know that his strength lies in the homes of the poor, is more than half the battle.

Let us look at the conditions confronting us in one of the large eastern cities. Like Philadelphia, Baltimore is fortunate in the absence of big tenement houses, but, like it, too, it has the disadvantage of a large number of very narrow streets and alleys. There is no drainage system, the sewerage is collected into cesspools, while the surface water and the water from the kitchens runs off on surface drains. There is a very large foreign population and a large number of colored people. While tuberculosis is a very common disease, I do not think the mortality in Baltimore is specially high. In the report of the Board of Health for the year 1901, there were 1,274 deaths from the disease in a total mortality of 10,479, about 12 per cent.

Four years ago two ladies, interested in the disease, gave me a sum of money to use in connection with our work at the Johns Hopkins Hospital. We do not take many cases of tuberculosis into the wards. Last year there were only 53. They come chiefly for the purpose of diagnosis, and we often admit patients from outside the city on purpose to teach them for a period of a week or ten days, just how to regulate their lives. It seemed best to try to do something for our consumptive out-patients, of whom we have an average of about 200 new cases in the year. It seemed to me that a good and useful work could be done by the personal visits of an intelligent woman to the houses of these patients, that she might show them exactly how to carry out the directions of the physician and give them instructions as to the care of the sputum, the preparation of food, and when necessary to report to the Charity Organization as to the need of special diet, or to the Health Board when the surroundings were specially unsanitary. In connection with this an inspection has been made of the condition under which these people live. Of the 726 cases, 545 were whites, and 181 blacks. Among the whites were 53 Russian Jews. There were 402 males, 234 females. The analysis of the reports of Miss Dutcher, Miss Blauvelt and Miss Rosencrantz during the past four years is briefly as follows:

	Russian	Colored	White
Bad sanitary location	62%	53%	16%
Insufficient light and ventilation	71%	65%	39%
Overcrowding	61%	41%	32%
Personal and household uncleanliness	70%	56%	30%

The white population in a large majority of the cases was distributed irregularly throughout the city, but a large proportion live in good loca-

tions, many even on new streets in the suburbs. A small percentage, about 20, live in a bad neighborhood, where the houses are close together and hemmed in in narrow alleys and courts. This region lies chiefly to the south and west of the hospital toward the harbor. In about a third of these people the personal and household cleanliness is fairly good. The colored people make up about a fourth of the cases. They live in much more unfavorable localities, chiefly in narrow, thickly populated and dirty alleys in small, two-story houses, usually old, and the windows often limited to the front—houses in which proper lighting and ventilation are impossible. One important feature in the colored population is the desire always to occupy their own houses, so that there is a comparatively little overcrowding. The Russian Jews form about one-fourteenth of the total number of patients. They live in a neighborhood that was at one time inhabited by the wealthier classes and the houses have now been converted into tenements. The streets are in many cases wide and clean and sunny. The percentage of overcrowding in the rooms is high. Very often a family of seven or eight is found in two rooms. The contrast in the matter of personal and household cleanliness between the Russians and the other whites is most striking. It is exceptional to find the former in a condition, either in person or house, that could be termed in any way cleanly. A very serious thing is the frequency with which the patients move from one place to another. The 726 patients had during their illnesses occupied 935 houses. Last year the percentage of removals was still higher. The 183 patients had occupied 379 houses. Another important point brought out was the fact that fully 66 per cent. of the patients visited did not sleep alone.

Amid such sanitary surroundings the patient can scarcely avoid contaminating the house in which he lives, while, perhaps more important still, the environment, combined with insufficient food, etc., lowers the resistance of the other members of the family and renders them more liable to active disease.

How are we to combat these conditions? *First,* by an educational health campaign in the homes. The young women who have been engaged in this work in Baltimore have frequently reported to me the readiness with which their suggestions have been accepted, particularly in regard to the care of the sputum. To be successful such a campaign must be carried out by the Board of Health, and a staff of trained visitors, women preferably, should do the work. To carry this out effectually there should be, *secondly,* in all cities a compulsory notification of cases. The plan has worked most successfully in New York, and it should be everywhere followed. There are no difficulties which cannot be readily surmounted, and there need be no hardships. *Thirdly,* in most cities the powers of the Health Boards should be greatly enlarged, so as to deal efficiently with the question of proper disinfection of the houses occupied by tuberculous patients. *Fourthly,* the question of the housing of the poor needs attention, particularly in the matter of proper control of tenements, and the regulation, by law, of the number of persons in each house. *Fifthly,* by placing upon the landlord the responsibility of providing, under the control of the Board of Health, a clean, wholesome house for a new tenant. *Sixthly,* the wholesale condemnation of unsanitary streets and blocks, and the rebuilding by the municipality, as has been done in Glasgow and elsewhere. We cannot make people cleanly or virtuous by act of the legislature, at the same time we cannot leave important sanitary details in the hands of irresponsible persons whose view of life is limited to returns and rentals. The extraordinary reduction in the mortality from consumption in the large cities is due directly to an improvement in environment. That much more remains to be done in the way of betterment the facts I have presented fully show.

III.

And then we have to face the all-important fact that at present an immense majority of all tuberculous patients have to be treated at home. Probably not 2 per cent. of the cases can take advantage of sanitarium or climatic treatment. What has the new knowledge to say to the 98 per cent., which is debarred from the enjoyment of these two great *adjutores vitæ?* Very much! Read aright, a message of hope to many. Just as we have learned that climate in itself is not the prime essential, but a method of life in any clime, so we have found that even under the most unfavorable surroundings many cases recover in town and country, if rigid system and routine are enforced. But "Hope, that comes to all," as the poet sings, comes not to the large proportion of the unhappy victims in our overgrown and crowded cities. What but feelings of despair can fill the mind in the contemplation of facts such as I have laid before you in the analysis of our inspection in Baltimore? So numerous are the patients that private beneficence shrinks at a task, which the city and State authorities have not yet mustered courage to attack, except in one or two places. Hospital care for advanced cases, sanitarium treatment for incipient cases can only be provided by an enormous expenditure, but we must not be discouraged, and the good work begun in Massachusetts, New York and in this State will grow and prosper. After all, the campaign in which we are engaged is one of education; only let us not forget that teaching has not all been on the side of the profession. We have all been at school during the past quarter of a century, and at school we must remain, at once teachers and pupils, if we are to make the knowledge we possess effective. We are not living in Utopia, and in the matter of sanitation the man on the street is a blundering, helpless creature whose lessons are put bodily into him at a heavy cost of life and health. You know this story only too well in Philadelphia. To provide accommo-

dation for all consumptives is impossible, but it is not unreasonable to look forward to the day when every large city will have a sanitarium for the treatment of the early cases, situated not far from its outskirts, with all the equipment for open-air treatment. Let there be some place at least where a poor workingman or working woman may have a chance for life. Now, as we doctors know only too well, hundreds are sacrificed in whom the disease could have been arrested. The hospital care of the very sick should be provided for in special wards of the city hospitals. To give the best of care to these unhappy victims is a true charity to them; to place them where they cease to be a danger to the general health is a true charity to others.

In the warfare against tuberculosis the man behind the gun is the general practitioner. The battle cannot be won unless he takes an active, aggressive, accurate part. That he is not always alert must be attributed in part to the carelessness which a routine life readily engenders, and partly to a failure to grasp the situation in individual cases. The two points to be impressed upon him are first, *that early recognition of the disease can only come from better methods of practice and greater attention to the art of diagnosis.* The insidiousness of the onset, the protean modes of advance, and the masked features of even serious cases should never be forgotten. As Garth so well puts it in his Dispensary (1699):

"Whilst meagre *Phthisis* gives a silent blow;
Her *strooks* are sure; but her advances slow.
No loud alarms, nor fierce assaults are shown,
She starves the *fortress* first, then takes the *town.*"

Too often precious time is wasted and the golden opportunity is lost by the failure of the physician to make a thorough examination of the chest. I am every day impressed with the necessity of more rigid, routine examination, even of the "ordinary case." In illustration of the carelessness which is so readily acquiesced in, let me mention a patient who was brought to me only a few weeks ago, supposed to have a protracted fever after typhoid. Her father, a physician, her husband a physician, and it is scarcely credible that neither of them had the faintest idea that the poor soul had advanced consumption, though it had reached a stage in which there was shrinkage of one side of the chest, and the diagnosis could almost be made by inspection alone. The carelessness is a sort of mental inadvertence, to which even the best of us at times seem liable. A very distinguished and careful physician brought his daughter to me a few years ago to have her blood examined, as he felt sure she had a chronic malaria. She had little or no cough, but an afternoon rise of temperature, and it turned out to be the usual story—quite pronounced local disease at her left apex. There had not been a suspicion on the part of her father or of the family.

On the other hand, we must be careful not to diagnose tuberculosis too readily. The physicians of our sanitaria have a good many tales to tell in this matter.

The second point is the *necessity for a more masterful management of the early cases.* Here comes in that personal equation so important in practice, and which has such a vital bearing in the prognosis of the disease. The dead hand of the Arabian still presses sore upon our practice, and precious weeks are too often lost in trusting to a polypharmacy which in some instances would make the heart of Avicenna or Averroes to rejoice. It may seem hard to say so, but my firm conviction is that more tuberculous patients are injured than helped by drugs. We have not yet come to the belief—to the practical belief, at any rate—that the disease is not to be *treated* by them. After so much has been written and spoken, one would suppose that the essential features of the treatment of the disease were generally recognized, but the practical experience of any man who sees a great deal of tuberculosis is directly to the contrary. It is not so much that the drugs do harm *per se,* but that weeks of priceless value are lost in trying to check a cough and quiet a fever in a patient who is allowed to continue his work and is up and about. I cannot agree with a recent writer who says that the tendency at present is rather to make too little than too much of medicinal treatment. Perhaps in advanced cases we are more sparing, but in early stages *I know* that we are still leaning on the Egyptian reed in which our fathers trusted and trusted in vain. Year by year I see only too many instances in which the mental attitude of the physician toward the disease clearly indicates that the idea of an efficient home treatment by fresh air had never been entertained. What I would like to plead for most earnestly is this home treatment of early cases by modern methods. I am not addressing myself now to city physicians. But I would appeal to the practitioners in the country and in the smaller towns and in the suburbs, where the conditions are so much more favorable. I have been much interested for several years past in a group of cases scattered all over the country, usually in the farmer or mechanic class, in which I have supervised with the physician a home treatment, often with striking success. The remarkable case which I reported in 1900 gave me great encouragement, as the complete arrest of the disease was accomplished under the most primitive surroundings by the persistence and devotion of the patient herself, who richly deserves the good health she enjoys to-day. There have been disappointments; all cases are not suitable, all cases are not curable, and it is not easy to say which ones are likely to do well. The most favorable looking patient with a small patch at one apex may have a progressive disease and die in the best of surroundings, while a case with high fever, sweats and an extensive lesion may improve rapidly. On November 24, a fine, stalwart fellow came to see me, in whom I did not recognize the *poitrinaire,* of September 28, carrying his diagnosis in his

face. The sunshine and open air of a Maryland village had been enough; enough, at any rate, to put him on the high road.

Let me mention in a few words the essentials in this home treatment of consumption in the small towns, country places and the suburbs of our large cities. *First,* the confidence of the patient, since confidence breeds hope; *secondly,* a masterful management on the part of the doctor; *thirdly,* persistence—*benefit is usually a matter of months, complete arrest a matter of years, absolute cure a matter of many years; fourthly,* sunshine by day; fresh air night and day; *fifthly,* rest while there is fever; *sixthly,* breadstuffs and milk, meat and eggs.

Let us not forget that it was a country practitioner, George Bodington, of the little town of Sutton Coldfields, in Warwickshire, who, in 1840, revived the open air treatment of tuberculosis. "To live in and breathe freely the open air, without being deterred by the wind or weather, is one important and essential remedy in arresting its progress—one about which there appears to have generally prevailed a groundless alarm lest the consumptive should take cold." And he gives a number of cases showing the good effects of the open air treatment. He seems to have carried it out on the plan which was so strongly advocated by Sydenham, which was a combination of open air and riding or carriage exercise. There are few things more striking in the writings of Sydenham than the insistence with which he states that consumption is curable. It is worth quoting a paragraph which I take from Locke's Anecdota Sydenhamiana, as it is put in a more striking way than in his general work. "I am sure that if any physician had a remedy for the cure of a phthisis of equal force with this of riding he might easily get what wealth he pleased: In a word, I have put very many upon this exercise in order to the cure of consumptions, and I can truly say I have missed the cure of very few; in so much that I think how fatal soever this disease be above all others, and how common soever; (for almost two-thirds that die of chronical diseases die of a phthisis), yet it is this way more certainly cured than most diseases of less moment: Provided always that this travelling be long persisted in according to the age of the patient, and length of the disease. . . . Women or very weak men that cannot ride on horseback may ride in a coach and yet attain the same end, as I have seen by often experience." In reality this practice of Sydenham never died out, but it was in practice in New England in the early days and throughout the eighteenth century. The late Henry I. Bowditch, who did so much to further the study of tuberculosis in this country, states that he followed it in his own case.

Let me conclude with a quotation from De Quincy, which puts in graphic language the question which so many generations have asked and asked in vain, but which we have been permitted to answer in part at any rate, and to answer in hope. "If you walk through a forest at certain seasons, you will see what is called a *blaze* of white paint upon certain *élite* of the trees marked out by the forester as ripe for the axe. Such a blaze, if the shadowy world could reveal its futurities, would be seen everywhere distributing its secret badges of cognizance amongst our youthful men and women. Of those that, in the expression of Pericles, constitute the vernal section of our population, what a multitudinous crowd would be seen to wear upon their foreheads the same sad ghastly blaze, or some equivalent symbol of dedication to an early grave. How appalling in its amount is this annual slaughter among those that should by birthright be specially the children of hope, and levied impartially from every rank of society! Is the income-tax or the poor-rate, faithful as each is to its regulating time-tables, paid by *any* class with as much punctuality as this premature *florilegium,* this gathering and rendering up of blighted blossoms by *all* classes? Then comes the startling question—that pierces the breaking hearts of so many thousand afflicted relatives: "Is there no remedy? Is there no palliation of the evil?" It is one of the greatest triumphs of scientific medicine to be able to reply, Yes, the evil may be palliated and is rapidly being lessened, and for many at least, a remedy has been found.

ORIGINAL ARTICLES.

SYPHILIS AND DIVORCE.

BY PRINCE A. MORROW, M.D.,
OF NEW YORK.

The relations of syphilis with marriage have a legal as well as a medical aspect. The introduction of syphilis into marriage entails not only physical damage to the health and life of the wife and children, but it involves a question of legal responsibility; divorce as well as disease may play a rôle in the domestic tragedy. The communication of syphilis in married life by one partner to the other, or even the exposure of one partner to contagion from the disease may affect (1) contracts to marry, (2) annulment of the union, and (3) divorce.

The ideas of most medical men as to the legal consequences of the existence or communication of venereal disease in the marriage relation are vague and incomplete; yet it is of the utmost importance that the physician should have an understanding of the law of marriage and divorce as applied to these diseases. In his efforts to persuade a syphilitic man to defer his marriage until it is safe, the physician should, if necessary, hold out as a threat the legal consequences incurred in transmitting his disease to his wife. This is not only a valid, but in many cases may be a sufficient argument in dissuading him against contracting a premature marriage. Then, again, the physician may be consulted by a married woman who has been infected by her husband and who confides to him her griefs, and at the same time her

determination to no longer live with a man who has done her this grave injury. In order that the physician may advise intelligently in a situation of this kind, he should be familiar with that branch of judicial law which relates to syphilis and divorce. He should know what the law accepts as good ground for divorce, what must be the concurrent conditions of its intervention, as well as the attendant disadvantages to the complainant which are inseparable from a suit for divorce in which syphilis is pleaded as a cause of action.

In many cases of marital infection rupture of the marriage occurs without an appeal to the law. The woman, on receiving proof of her husband's infidelity in the shape of venereal disease, abruptly leaves the conjugal bed and returns to the paternal roof. In other cases there is an effective separation between the husband and wife while the outward appearances of the marriage relation are still preserved.

We may now inquire what redress the law affords a woman who has been infected by her husband with syphilis in the marriage relation.

In the first place, it is to be observed that the mere existence of venereal disease in one partner, or even its communication to the other, does not *per se* constitute sufficient ground for divorce. There must be certain concurrent conditions of an aggravating character presently to be considered.

It is to be noted that in no civil code is venereal disease specifically mentioned as a statutory ground for divorce, nor is there any penalty laid down for its transmission. The word "syphilis" nowhere appears upon the statute books of this or any other country. The nearest approach to it is in the civil code of Kentucky, in which it is stated that the contraction of a loathsome disease by one of the spouses is a specific ground for divorce, and it has been held that venereal disease is included under the term "loathsome disease."

The absence of any specific legislation in the matter of the transmission of syphilis may at first sight appear to the medical man as evidence of the failure of the law to recognize the grave physical injury which may result from the communication of this disease. The wisdom of the law is, it is claimed, shown in the laying down of certain general principles, the application of which is left to the judgment of the court according to the circumstances of the particular case. If syphilis always bore the stamp of immorality; if it were exclusively contracted by impure intercourse before marriage or through adulterous relations after marriage, there would be some grounds for this criticism, but, as is well known, syphilis is not necessarily a venereal disease; it may be contracted accidentally through various professional and industrial relations, and it may be innocently communicated by one partner to the other in marriage. If the code specifically decreed that one partner might demand a divorce because of syphilis communicated by the other, the strict construction of the law might work great injustice, as, for example, in the numerous cases recorded where a nurse has acquired the disease from a syphilitic nursling, and has communicated it to her husband. In such cases the woman may be entirely ignorant of the nature of her disease, and cannot be held either morally or legally responsible. In cases of *unconscious syphilis* the responsibility of the conjoint who gives the syphilis is legally as well as morally attenuated.

Fournier reports the case of a physician who presented a chancre of the tonsil after having put in his mouth a paper cutter, which he had previously used as a tongue depressor in examining the throat of a patient; the nature of the chancre was not recognized, and he communicated syphilis to his wife. The law cannot foresee or provide against these possible contingencies, and it perhaps wisely includes the offence under some general rather than under a specific statute.

In order to give a clear understanding of the legal relations of syphilis with marriage, the writer has endeavored to present a digest of the decisions in some of the more important cases which have come before the courts for adjudication, from which deductions may be drawn as to the spirit of the law and the general rule or practice in dealing with cases of this character.

For the citation of cases and rulings which have come before the courts in this country the writer is indebted to a paper in a recent number of the *American Law Review* by C. F. Huberich, of the University of Texas, on "Venereal Disease in the Law of Marriage and Divorce," and to the admirable monograph of Thibierge on *Syphilis et Deontologie*, for a knowledge of the present position of jurisprudence in France in relation to syphilis and divorce.

While the principles which underlie the decisions made by different tribunals are practically the same, the rulings are not uniform and appear to be somewhat contradictory. This is not surprising in view of the varying circumstances and accessory conditions which attend the transmission of venereal disease in the marriage relation. Some of these circumstances are held to aggravate, others to mitigate the responsibility of the offender, and they must all be taken into consideration and given due weight in arriving at a decision. Special cognizance is always taken of that cardinal principle of equity which guides the administration of justice in all actions involving civil or criminal responsibility—*viz.*, whether the act charged has been committed *knowingly and wilfully*.

While syphilis is not specifically mentioned as a cause for divorce in the statute books, actions for divorce may be instituted upon the ground of "cruelty," as it is generally held by the American and English courts that the communication of this disease constitutes cruelty, which is a statutory ground for divorce. The French courts provide that one partner may demand divorce from the other on the ground of "grave injury,"

and, since the communication of syphilis in marriage is held to be a grave injury, proceedings for divorce are usually instituted upon this ground or upon the ground of infidelity. The civil codes of almost all civilized countries recognize infidelity as sufficient ground for divorce, and, if this charge can be proven, the graver injury of syphilitic infection is usually passed over in silence.

Contract to Marry.—The existence of venereal disease in either party to a contract to marry is sufficient ground for the other party to refuse to fulfil the engagement, and therefore constitutes a valid defence in a breach-of-promise suit. Although this point has not been judicially determined in England, it has been laid down as a general rule that if the condition of the parties was changed after the making of the contract it was good ground for either to break off the engagement.

Few actions have been brought for breach of promise in which this defence was set up, as an indication of the line of defence would be quite sufficient to induce any respectable or self-respecting woman to discontinue the suit. Still, such cases have come before the courts in this country for adjudication where the defendant in a breach-of-promise suit refused to perform the contract on account of the existence of a venereal disease in himself.

The rule of the law as given by Huberich is that where a venereal disease is contracted prior to, but was not known to exist at the time the contract to marry was entered into, or when such disease is contracted subsequent to the making of the contract to marry, but through no wrongful act on the part of the defendant, its existence furnishes a good defence for an action of breach of promise. In his ruling in one of the cases just described, the judge states:

"We cannot understand how one can be liable for not fulfilling a contract when the very performance thereof would in itself amount to a very grave crime not only against the individual, but against society itself. . . . The law will constrain no man to assume a position so full of peril as to place within his reach the lawful means of gratifying a powerful passion at the risk of another's health or life, and the possibility of bringing into the world children in whose constitution the seeds of a father's sin shall lurk."

As a Ground for Annulment.—The existence of a venereal disease in either party at the time of the marriage may render the marriage voidable. The annulment of the union in such cases would seem to be based upon the rule of the law which recognizes permanent and incurable impotency sufficient ground for divorce. In one of the cases the ruling was, that "while there was no such malformation which renders complete sexual intercourse impossible, there was a physical reason that rendered her (the defendant) incapable of healthy coition. Every such act, by reason of her physical condition, was attended with great danger of communicating to him incurable disease and endangering his health and life. . . . In the case at bar the petitionee's organs of generation were at the time of marriage in an incurably diseased condition, which, while it did not physically render her incapable of copulation or of bringing into life a child a mass of syphilitic sores, as good as dead when born, yet it did render copulation and procreation on the part of the petitioner impracticable, because the act endangered both his health and life."

In a noted New Jersey case the marriage was annulled on the ground of "fraud." The man had syphilis, although he had assured his intended that he had never had venereal disease. Upon discovering his deception she brought suit for the annulment of the marriage.

The court held that "to annul a marriage for a fraudulent representation inducing the contract it must be shown that the fraud affected an essential of the marriage. An explicit statement by a man about to be married that he was not affected by the loathsome disease called syphilis, made when it was his duty to state the truth, and knowingly false, is such a fraudulent representation as affects an essential of the marriage relation."

"The decree cannot be had upon the uncorroborated evidence of the complainant. The contract of marriage is one of exceptional and peculiar character. On the grounds of public policy the State has an interest in the status created by a marriage contract, and when made it can only be dissolved on grounds and by judicial proceedings sanctioned by law."

In the above case it was proven by the testimony of the physician who had treated him that the man had syphilis and was informed of the nature of his disease.

In another case, in which an action for the annulment of marriage brought by the wife on the ground that the defendant was constitutionally affected with syphilis, and where he had knowledge of his condition at the time he entered marriage, but failed to inform plaintiff of the fact, and she, immediately upon learning of it, and before the marriage was consummated, left him and refused to live with him as his wife, it was held that "his concealed disease was such as would leave with him no foundation upon which the marriage relation could properly rest; that the libellant could not live with him as his wife without making a victim of herself for life and giving to her offspring, if she had any, an inheritance of disease and suffering. Few, if any, would be bold enough to say that it was the duty of the libellant on discovery of the fraud before consummation of the marriage, to give herself up as a sacrifice and to become a party to the transmission of such a disease to her posterity."

In another case annulment was decreed, although the parties had continued to cohabit after the nature of the defendant's disease became known to the plaintiff. It was expressly held that such continuance of cohabitation could not be regarded as a condonation.

Divorce.—"To constitute a ground of cruelty it is usually required that the disease should have

been actually communicated to the complainant; that the complainant should have been ignorant of the existence or nature of the plaintiff's disease at the time of its communication, and that the defendant should have infected the petitioner knowingly and wilfully. If all these facts concur, no question of the propriety of granting the divorce can arise unless there are facts showing condonation of the offense" (Huberich).

The weight of authority is that the disease must be actually communicated.

Dr. Lushington rules as follows: "However great the moral delinquency of consummating a marriage with the probable chance of communicating the venereal infection, I am not prepared to say that so doing constitutes legally an act of cruelty as understood in these courts. In order to constitute an act of legal cruelty there must be, in my opinion, an actual communication of the disease, and the running of the risk is not sufficient."

Lord Stowell held that "attempted intercourse with the complainant when the defendant was afflicted with a contagious disease would suffice to sustain a charge of cruelty."

In still another decision it was held that "a reasonable apprehension of injury is sufficient, and the complainant need not wait until the wrongful act is committed."

Justice Key, in a case before the Texas Court of Appeals, states: "A man may, as a result of his own debauchery, become so diseased as that living and cohabiting with him will probably destroy the health of his wife, and we are not prepared to say that such fact would not, of itself, entitle a pure and innocent woman to a divorce, in the absence of specific proof that he had communicated to her a loathsome venereal disease."

In the courts of this country stress is laid upon ignorance of the existence or nature of the disease on the part of the complainant. In one case in which the wife was informed of the disease of her husband and of its contagious nature, but continued for a year and down to the last moment of their living together to submit willingly to his embraces, she was denied a divorce.

On the contrary, where the complainant is ignorant of the nature of the plaintiff's disease, no case of waiver or condonation arises. A divorce was granted in a case where the husband had communicated syphilis to his wife, but had ascribed her syphilitic sore-throat to drinking from an infected vessel, and continued marital relations with her.

In the French courts no stress is apparently laid upon this point, as it is hardly to be assumed that a woman would marry a man knowing him to be syphilitic or permit a consummation of the marriage unless through violence.

The French tribunals "consider the transmission of syphilis in marriage a grave injury and a cause of separation, whether the husband had been attacked before or after marriage, and attach the same gravity to the simple fact of exposing the conjoint to the contraction of this malady when the husband knows he had been attacked and recognized its contagious nature."

In all courts of law especial stress is laid upon the knowing and wilful communication of the disease. The defendant must know that he had an infectious disease and that it was attended with danger of infecting the other party, and it is a question for the courts to decide whether the defendant's statements upon this point are entitled to credence. Also when the defendant believes himself cured at the time when the infection is alleged to have taken place, he is not guilty of cruelty.

The Texas Court of Appeals held that lack of knowledge on the part of the defendant as to his condition merely renders his conduct less culpable.

It has been held that "the mere fact that the husband has communicated disease to his wife, whatever may be thought of it in other points of view, is not enough to constitute legal cruelty. It is abundantly clear that for this purpose the act must be a wilful one. Wilfulness may, however, be generally inferred from the fact of communication coupled with the knowledge on the part of the defendant of the existence of the disease in himself." It is to be understood that wilfulness does not imply a wish or intent to injure.

"If a man, knowing that he was suffering from a complaint of that sort, had intercourse with his wife and did communicate it to her, even although he were to swear, and you were to believe him, that he did not mean to communicate it, I doubt whether you ought not to say that he had been guilty of cruelty. If he knew that his body was tainted and that he might communicate the disease; if he knew that he was running the risk of giving his wife the complaint from which he was suffering, and he did give it to her, I am disposed to think that it would be an act of cruelty." "Whoever does an act likely to produce injury, and injury follows, can never excuse himself by saying that he hoped a probable consequence might, by some good fortune, not follow."

A long series of decisions of the French courts might be quoted establishing the fact that syphilis is a cause for divorce, at least in a case where the disease has been knowingly communicated. The fact that the husband had before marriage a venereal malady and communicated it knowingly to his wife, represents to her alone an injury of sufficient gravity to justify divorce. On the other hand, it has been decided that a wife cannot demand divorce for having been infected with a venereal disease when it is not established that it had been knowingly communicated by her husband. Also that the communication of syphilitic disease to the wife by the husband is not a cause for *separation de corps* when at the moment of his marriage he believes himself cured and that the communication of his disease had been involuntary.

The French courts attach an especial importance as to whether the disease of the husband was contracted posterior to marriage on the general principle that the acts of the spouse anterior

to marriage cannot in principle serve as a basis for an action for divorce. Exception to this principle has been made, however, in certain decisions in cases of transmission of syphilis.

It will be seen that the "concurrent conditions" upon which decisions are based are practically the same in all courts of justice. There are certain circumstances, however, which are held to aggravate or attenuate the charge of cruelty or grave injury. The French tribunals admit different degrees of responsibility in persons introducing syphilis into marriage.

First, it has been held as an aggravating circumstance that the disease has been communicated soon after marriage or in the first approaches.

Second, if the husband has transmitted the disease in conjugal relations imposed by marriage.

It has been held by an English court that an attempted intercourse, the husband forcing his wife to his bed, when he was afflicted with venereal disease, would suffice to constitute a charge of cruelty, although the disease was not actually communicated. It is also regarded as an aggravating circumstance when there is reason to believe that an infant conceived as a result of these relations will be born tainted with the disease.

The responsibility of the husband is increased when he has made no attempt to repair the damage to his wife's health by securing proper medical treatment, and especially when he has placed obstacles in her way of obtaining proper treatment, or sacrificed the care of her health to "false shame." On the other hand, it is regarded as a mitigating circumstance if the husband has promptly employed every means to secure proper and efficient treatment.

It would seem that the gravity of the accidents or the more or less severe results of the infection to the wife is not held by the courts as affecting the responsibility of the husband, as there is no question of damages or penal responsibility.

From this survey of the jurisprudence of syphilis and divorce it appears that when a woman has been infected with syphilis by her husband the law may grant her a divorce on the statutory ground of cruelty or infidelity. In the State of New York, where "infidelity" is recognized as the sole ground for divorce, the charge of cruelty could not be pleaded.

Under the present conditions of the law the physician should advise his patient that syphilis should never be invoked as a cause of action for divorce unless it constitutes the chief or only phase of cruelty that can be alleged. The charge of infidelity, if it can be sustained, should always be the preferential plea. Infidelity on the part of the husband is in no sense a reflection upon his wife. The guilt, as well as the dishonor, rests upon the husband. The syphilis should be hidden, as it is not necessary to play this incriminating card. It does not affect the result, and when brought forward is ignored by the jurist. If the fact is pleaded and established in the public courts that a woman has been made the recipient of a loathsome disease which is regarded as incurable and transmissible to her children, even if she is successful in gaining her suit, she must be branded as the bearer of a shameful disease, and her children, if she have any, must bear through life the stigma of syphilis.

The woman who seeks a divorce upon the plea of syphilitic infection by her husband should be fully informed of the ordeal before her. In the first place, it is necessary to furnish legal proof. While the existence of syphilis in the wife may appear as *prima facie* evidence that she has received it from her husband, it is by no means conclusive to the courts. She must prove (1) that her husband has syphilis; (2) that she has syphilis; (3) that the syphilis of the husband is the origin of her own. She must reveal certain secrets of private life, often disgusting details of shameful indignities to her person; she must be prepared to face the inevitable scandal, the disgrace and publicity of divorce proceedings; she must appear in court or before a referee and testify to humiliating experiences, which are not always carefully guarded from the public. If her husband defends the suit he may falsely plead as a mitigating circumstance that he thought he was cured, did not know his disease was contagious, that the contagion was involuntary, etc. Even if successful, she will find that she has purchased her freedom at the price of humiliation and shame. The only punishment imposed upon the guilty perpetrator of the wrong is that he is denied the further privilege of dishonoring his wife's body. No wonder that many women, seeing no way of escape open, and realizing that the harm is done and cannot be undone, accept their fate and philosophically make the best of it.

Still, there are many cases of marital infection of such aggravating character that the self-respecting wife finds her situation simply intolerable and not to be endured. She feels that she must escape at any cost from the bonds that bind her to a man by whom she has been dishonored and diseased.

As the law now stands there is no civil or penal responsibility imposed upon the husband for the transmission of syphilis in the marriage relation. In addition, there are so many concurrent conditions to be complied with, so many loopholes of escape for the guilty partner from the elastic interpretation of what constitutes "knowing and wilful" communication, so many extenuating circumstances that may be pleaded, such as "I did not know I had the disease;" "I thought I was cured," etc., that the existing laws do not constitute a sufficient protection. The question of the practical wisdom of a specific statute penalizing the transmission of venereal disease in marriage will be elswhere considered.*

In regard to the physician's line of conduct in the matter of syphilis and divorce, it is rarely advisable that he should appear in the interests of his patient. The proof of the communication of

* Social Diseases and Marriage, now in press.

the disease can be furnished by a medical expert appointed by the court for the purpose of making an investigation. If the physician has treated the wife, his prescriptions are always available in furnishing presumptive proof, at least, of the nature of the disease for which he has treated her. Especially should the attending physician not give a letter or certificate that she has syphilis and that he is treating her for it. In the first place, he may be the physician of both husband and wife, and should he give a certificate it would betray the secret the husband confided in him. In the second place, certificates of this character are looked upon with suspicion, and have even been rejected by the courts.

SOME PRACTICAL SUGGESTIONS ON PHYSICAL EDUCATION IN THE PUBLIC SCHOOLS.

BY RICHARD COLE NEWTON, M.D.,
MONTCLAIR, N. J.

At the last meeting of the American Academy of Medicine, Hon. William T. Harris, U. S. Commissioner of Education, called attention to the present desultory and often injurious methods of teaching and practising gymnastics in the public schools; laying particular stress upon the fact that from a lack of proper medical knowledge on the part of the instructors, the pupils were liable to injury instead of benefit from these exercises.

The import of his remarks was that only from the medical profession can a remedy for this and other evils in the present system, or perhaps, I should say want of system, in the physical education of children, be expected.

An editorial in *American Medicine* (March 7, 1903) is so apposite that I cannot refrain from quoting from it: "As vigorous health and its accompanying high spirits are larger elements of happiness than any other things whatsoever, the teaching how to maintain them is a teaching that should yield in moment to none other whatever." Taking these famous words of Herbert Spencer's as a text, our editor proceeds to preach an excellent and pithy sermon on the physical education of the young. He says among other things, "It is not desirable to produce athletes, physical culture fanatics or practitioners of new-fangled and erratic 'systems' and 'pathies,' what is needed is simple instruction in the proper care and use of the body," . . . "and we strongly urge more literature and personal explanation from the American medical profession. The subject is much too important to be left entirely in the hands of lay teachers and writers." There is no question about the truth and reasonableness of these remarks, but they do not go far enough. Essays on education are of no use to a child of four, nor does a knowledge of physiology give one a good digestion; what I have tried to point out elsewhere,* and what a recent editorial writer in the *Lancet* demands is, that physical education should be practically applied and should be made not alone commensurate with mental education, but preliminary to it. At least educational systems should be so arranged that scholars who are unfit physically, or who are begining to show any evidence of physical breakdown from mental overwork, should be turned over to the doctor, who shall have the power to modify or even suspend all mental work until the bodily condition can be brought up to the standard average for the age of the particular child. Mental injury to the growing child is so insidious in its inception, and may be so long battled against with more or less success by the ambitious and painstaking scholar, that as a rule, the teacher will utterly fail to detect it, until irreparable damage shall have been done. Hence it is indispensable that the doctor should have a controlling voice in the education of young children. It is not perhaps necessary to enlarge on the theoretical aspect of this question; I can only say that the practical unanimity among educators in the opinion that some working rules must be formulated, for the promotion and preservation of the health of scholars is a convincing proof of the necessity for such rules Many, if not all, of the teachers are looking to us for help. In the first place then, I would lay down as rule number one, that no scholar should be admitted to the regular course in the public schools under seven years of age, eight would be better. The "eminent physiologist" quoted by Spencer, who asserted that eight years of age is as young as study in school should begin, was unquestionably right, and, so far as I know, this assertion has never been gainsaid by any scientific man. It is true that the public schools demand our children at three and a half or four for the kindergarten, and at five many of them begin the regular graded course. This is at least two years too young, and is often the foundation of the nervousness and mental breakdown of after years. Quoting Spencer again, "There is a given order in which and a given rate at which the faculties unfold, if the course of study conforms itself to that order and that rate, well . . . Nature is a strict accountant . . . If you will let her follow her own course, taking care to supply in right quantities and kinds the raw materials of bodily and mental growth required at each age, she will eventually produce an individual more or less evenly developed." And that is what the ideal education is, an even development of one's powers, moral, mental and physical. Having now started the child in the public school at the age of seven, or eight, medical supervision of him should never cease until he graduates at, say eighteen. A number of educators have told me that at least ten per cent. of all the scholars in American public schools are defectives either mentally, or physically. These can only be separated and properly classified by a competent medical examiner. A large percentage of these are probably suffering from faucial adenoids, others from defective eye-

* Deep Breathing. New York Medical Journal and Philadelphia Medical Journal, Nov. 7, 1903; Why Is Modern School Life Especially Disastrous to Girls? Medical Record, Sept. 6, 1902; The Doctor and the School Teacher. Medical Record, Oct. 18, 1902.

sight, others are deaf, others are rickety, etc. None of these conditions are hopeless. And judicious advice and treatment at the proper time might be of inestimable advantage to the unfortunate scholar, and might save permanent injury and perhaps a lifetime of suffering.

I have purposely omitted contagious diseases from the above partial list, because the necessity of medical inspection of schools to detect and segregate cases of trachoma, ringworm, scabies, syphilis, and so on, and the whole list of exanthemata with diphtheria and pertussis, is now generally acknowledged, and in many cases at least, health boards have succeeeded in having inspectors appointed, who shall visit the schools daily or as often as possible, for the purpose of discovering and isolating cases of contagious disease.

The medical inspection, however, should not cease at this point, but should extend to the examination and record of the physical condition of every scholar, the age, height, weight and lung capacity, and the condition of the teeth, eyes, ears, method of breathing, whether oral or nasal, etc., should be observed and recorded and a copy of the record should in every case be sent to the parents and to the family medical adviser. At least once in three months, this examination should be repeated and the results carefully recorded and compared with the record of three months before and these reports should go to the parents just as regularly and faithfully as the reports of scholarship. The work already done in the Boston and Chicago schools is most valuable and promises excellent results. The tables of height and weight of scholars at different ages so carefully worked out by Dr. Christopher, of Chicago, cannot fail to be a valuable guide to medical inspectors of schools.

I might call attention to the early discovery and probable rectification of scoliosis by this method. It has been asserted that four out of five educated women have more or less scoliosis. Whether this is true or not, the percentage of sufferers from this deformity is needlessly large, and could be, to a great extent, prevented by such a system of medical inspection of schools as I have outlined.

How shall we provide for this general school inspection, and how shall competent medical men be induced to give up sufficient time and thought to the proper execution of these duties? This is an extremely difficult question. Perhaps the suggestion of Dr. Cook, made in his address as chairman of the Section of Diseases of Children at the last meeting of the American Medical Association, is as good a one as we can adopt, viz., that in each State a commission of five members be appointed, at least two of whom shall be physicians, this commission shall have jurisdiction over all questions of physical education and child labor. The members of this commission shall be appointed by the judges of the Supreme Court of the State. The said commission shall appoint inspectors, who shall see that all laws relating to the public schools and to child labor are properly executed and shall report regularly on all hygienic matters connected with the public schools and public education, as well as make the reports now required by law in many States as to the hygienic condition of factories, etc. The appointment of the commissioners by the judges of the highest State court, Dr. Cook esteems an especially valuable feature, as it will probably forever remove the questions of child labor and the execution of the truant laws, etc., from the domain of petty politics, and vicious contract labor.

It seems odd by the way, that we pass laws to prevent the poor man from sending his child to work too young, while we sacrifice the health and wellbeing of our own children by an injudicious and often improperly administered system of public school education.

An attempt more or less efficient is made in many public schools to give physical instruction regularly, but so far as I am aware, no competent physician oversees and controls this instruction. The poor children are liable to be made and often are made the victims of some ill-advised or poorly worked out theory or fad. Furthermore, no medical supervisor, as a rule, watches the children at the time of their exercises, who is competent to decide whether any of them are being injured by the exercises. Cases of congenital heart disease, emphysema, diabetes, Menière's disease, etc., may be found among the scholars. They must be separated and treated as each individual case requires, and there is no way of detecting and classifying all of these diseased conditions in the public schools, except by the regularly recurring medical examination and record of every single pupil, as outlined above. With the large present outlay of money in the public schools,* the hiring of a competent medical man for each 1,000 or 2,000 pupils can easily be borne, especially if the often repeated advice to simplify the courses of study be carried out.

So that a number of teachers of the ornamental and superfluous branches may be dispensed with and the money now used for their salaries may be spent in hiring the necessary medical inspectors and buying more apparatus, etc., by this means the scholars may have more systematic and efficient physical instruction. The time is ripe for action and any good, practical plan which shall modify the present indiscriminate and often injurious educational methods, both mental and physical, will meet with the approval of (1) the children, (2) the parents, (3) the profession, and lastly, as I know from interviews with many friends among them, from the conscientious overworked teachers. If the latter can shift the responsibility of the care of the health and physical development of the scholars to the shoulders of our profession, where it unquestionably belongs, it will considerably lighten the burdens and anxieties of

* According to the last report of the Commissioner of Education, the United States spent for the school year 1900-'01 $222,043,236 on elementary education.

an overworked and underpaid and frequently unappreciated class in the community.

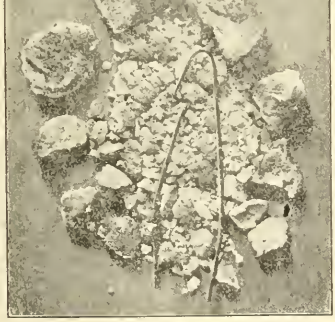
The duty of the medical profession is plain and there can be no question that the advanced educators will unite with us in any well-considered and practical scheme for conserving the health of the scholars by first forestalling injury from any preventable cause, and secondly, by instituting and maintaining an efficient system of physical education.

REPORT OF CASES WITH EXHIBITION OF SPECIMENS DIAGNOSED BY THE CYSTOSCOPE.

BY JOHN R. WATHEN, A.B., M.D.,
OF LOUISVILLE, KY.:
PROFESSOR OF SURGERY IN KENTUCKY SCHOOL OF MEDICINE; SURGEON TO ST. ANTHONY'S HOSPITAL, LOUISVILLE CITY HOSPITAL AND KENTUCKY SCHOOL OF MEDICINE HOSPITAL, LOUISVILLE, KENTUCKY

The importance of careful examination of the bladder, accompanied by catheterization of the ureters, with the electric cystoscope in all doubtful or stubborn cases, is too well appreciated to need emphasis before this Society. The following brief report of a few cases, on account of certain features of interest, are taken from a list of 126 bladder cases, examined for diagnosis, and will illustrate the importance of this method of diagnosis:

Case I.—Miss B., aged twenty-four years. Referred by Dr. Hall. Examined and operated upon



Specimen of Case I.

at St. Anthony's Hospital. Patient had complained of severe cystitis for about 2½ years; had bladder irrigated repeatedly with antiseptics, and had taken much urotropin and salol, with little benefit. Upon examination with the cystoscope, I discovered a calculus as large as a hen's egg, and through its center, imbedded in the calculus, was a hairpin. This settled the diagnosis, and upon questioning the patient, she admitted for the first time that she had had considerable irritability of the urethra from early childhood, and had often relieved the irritation by using the hairpin, until it slipped into the bladder. The patient was anesthetized, and the urethra dilated until I could introduce a large forceps and crush the stone. I then introduced a large Kelly endoscope, and by means of reflected light removed the pin and the pieces of the calculus. I then thoroughly irrigated the bladder to remove every particle of stone, and finally dilated the bladder with water, and examined with the Nitze cystoscope to see if I had overlooked any pieces. The patient was placed on urinary antiseptics, and within one week left the hospital entirely cured.

Case II.—Mrs. K., aged sixty years. Consultation with Dr. Speidel at patient's home. She had complained of frequent hemorrhages from the bladder for over a year. Upon examination with the cystoscope I discovered a large bald tumor on the posterior wall of the bladder. This tumor would bleed when touched with the beak of the cystoscope. Considering the size and type of the tumor, I did not advise an operation, but injected small quantities of alum water and adrenal solution, with some benefit. About four months later she died. Had we made a diagnosis earlier, the growth could probably have been successfully removed.

Case III.—Mrs. P., aged forty years. Patient seen during my service at Louisville City Hospital. Complained of chronic cystitis of several months' standing. Examined bladder carefully with the cystoscope, and found pus coming from the ureter on right side, with clear urine on left side. No need for a catheterization of ureters, as the pus was thick, and easily seen on the right side. This evidence caused me to examine in the region of the kidney on the affected side, and I discovered a large tumor. Patient was later anes-

Specimen of Case III.

thetized and laparotomy performed. The large hydropyonephrotic kidney had dissected up the mesocolon, and by making an incision in the outer

side of the ascending colon, I was able to reach the kidney. This organ I walled off from the other structures with gauze, and carefully removed the fluid contents of the kidney and its partially occluded pelvis by aspiration. I then with ease removed the contracted kidney, and as much of the sacculated and strictured ureter as possible. No stones were found either in the kidney, pelvis or ureter. The other kidney was normal in appearance. The patient did well for about a week, and then died from suppression of urine. I believe this patient would have been saved if diagnosed earlier.

Case IV.—Miss H., aged twenty-seven years Patient seen during my service at Louisville City Hospital. Complained of chronic cystitis. Examined with cystoscope and discovered a large silk ligature imbedded in bladder-wall, on left side, above orifice of ureter. This I removed through a Kelly endoscopic tube, and in a short while the cystitis disappeared. The patient gave a previous history of having been operated on for ovarian tumor on the left side.

Case V.—Mrs. C., aged thirty-five years. Patient seen in consultation with Dr. W. H. Wathen at St. Joseph's Infirmary. She had complained of a chronic cystitis and pain on one side for about a year, and the diagnosis by her general practitioner was tuberculosis of the kidney. Upon examination with the cystoscope, the bladder-wall was found pushed over to one side, and a small sinus discharging pus into the bladder, clearly demonstrating a pelvic abscess, which with bimanual examination was difficult to diagnose or locate. Operation per vaginam confirmed the diagnosis, and a large quantity of pus was evacuated from a pus sac or cavity situated high up in the pelvis. After this the patient made a nice recovery.

Conclusions.—These few selected cases illustrate the necessity for more thorough and accurate methods of diagnosis in this important field of work. Of my 126 cases examined with the cystoscope on account of obscure diagnosis, I catheterized the ureters in 23 cases, failed to do so for various complications in 12 others, and for the remaining 91 I did not need to catheterize to make a diagnosis

HYSTERIA.

BY WILLIAM B. YOUNG, A.M., M.D.,
OF BON AIR, TENN.;
PRESIDENT MIDDLE TENNESSEE MEDICAL SOCIETY; EX-PRESIDENT UPPER CUMBERLAND MEDICAL SOCIETY.

If Egyptologists have correctly translated hieroglyphics, hysteria existed among the people of the most ancient civilization. From this early period to the present the affection has been known under various names—trances, visions, vapors, hysterics, hyppoes and numerous Latin synonyms, most of which "have reference to the supposed uterine origin of the disease." The name hysteria comes from a Greek word that means uterus. The term is quite significant of the belief our forefathers in medicine had in regard to the seat of the disease.

I shall not bore you with the symptomatology, diagnosis and prognosis of hysteria. They are too well known, even by the medical student, to justify a repetition in a paper of this kind. My remarks will be devoted entirely to the etiology, pathology and treatment—three very "uncertain quantities."

We all know that the true etiology has never been discovered, or, at least, there is but one point in regard to the primary cause about which all of the authorities agree—that heredity is the most important factor in the production of hysteria. A study of the history of hysterical phenomena and my own observation teaches me that even this "point in common" is not well taken. That heredity plays a part (but a very insignificant one) no informed physician will call in question. There are sufficient evidences occurring in our every-day practice, if we would but observe and ponder over them, to convince any physician, it seems to me, that conscious and unconscious imitation is decidedly the greatest factor in the etiology of hysteria. Take, if you please, the history of medicine and study closely the numerous epidemics and endemics of hysteria. Mills tells us that "no country within the range of medical observation has been entirely free from them. Communities civilized and semicivilized, Christian and Mohammedan, Protestant and Catholic, have had a fair share of the visitations." The visions and trances of the ancients were peculiar forms of hysteria. The "dancing mania" of the Middle Ages, that spread over a good part of Europe, is another singular manifestation of this psychosis. That most wonderful psychic phenomena of history, the Crusades, which Hume says "has ever engaged the curiosity of mankind, as the most signal and most durable monument of human folly that has yet appeared in any age or nation," is but another form of hysteria.

Those religiohysterical disorders, "the jumps, jerks and convulsions" of the good old camp-meeting are strange phenomena which we have all witnessed at the dawn of the twentieth century. How many endemics of convulsions and peculiar hysterical manifestations have been reported from hospitals, orphan homes and the various health resorts, which were produced by the inmates unconsciously imitating the hysterical phenomena of the first victim? Who can contemplate the rapidity with which the dancing mania and the fire of the Crusader spread from town to town, nation to nation and continent to continent, and not believe that unconscious imitation is the most powerful factor in the etiology of hysteria?

It seems to me that alienists, in looking for the primary cause of hysteria, have entirely overlooked the history of the early mental training of the individual. They find most usually that the grandmother, mother or some relative had hysteria, therefore they conclude that it must be hereditary. From a study of the previous life of the

cases coming under my observation, I am convinced that the pernicious training of the psychical element of the patient during infancy and childhood has much more to do with the production of hysteria than heredity.

There are few parents who appreciate the great importance of properly training the unconscious mind of infancy and childhood. Psychologists tells us that this is by far the most critical period of the life of the individual. Dr. Schofield in his late work, "The Unconscious Mind," says: "All around the child lie countless forces, unnoticed and unknown by the parent, while within the child lies a vast receptive capacity, unknown to the parent, and still largely ignored by these psychologists who should be his teachers—the unconscious mind; and it is to the action of these unnoticed forces upon the ignored mind that the child's real early education and character are mainly due." Dr. Waldstein, speaking of the great importance of a proper environment for early childhood, says: "What is often called heredity is simply the expression of a subconscious self, the beginning of which can be traced to early childhood, when the actions of their parents and their example are subconsciously perceived, and by their constant repetition form fundamental impressions."

Herbert Spencer said: "A man resembles far more the company he keeps than that from which he descends." Sir Michael Foster, the great physiologist, in the *British Medical Journal* of August 21, 1897, while speaking of the manner in which physiology deals with the muscular vascular and glandular parts of the body, says: "Nor does she do otherwise when she comes to deal with the nervous tissues. Nay, it is the very prerogative of these nervous tissues that their life is above that of all the other tissues, contingent on environment and susceptibility of education." S. Weir Mitchell says: "There exists in all of us, feebler in age and more potent in childhood, a tendency to automatic and unconscious imitation which is the parent of a good deal of mimicry of disease." Pryor is quoted by Dr. Schofield as saying: "Every look, every word, every movement is without the knowledge of the mother or nurse, suggestive to the child, *i.e.*, they determine his mental representation, and, later, his actions."

When we learn from such noted biologists and from every-day observation the paramount importance of a judicious environment for the receptive plastic mind of infancy and childhood, is it any wonder that the daughter, who is a constant companion of the hysterical mother from birth to advanced girlhood, should breathe in the contagious atmosphere in which she is completely submerged? Is it necessary for us to appeal to heredity for a philosophical reason why hysteria is a disease peculiar to the female? We should not think it strange that some cases of hysteria do not develop until middle age or late in life and thereby attribute it to a "neurosis," a term as indefinite as the diagnosis of eczema by the colored M.D., "a cutaneous affection of the skin." The majority of such cases, if the true history could be known, would reveal the fact that hysterical impressions were left on the unconscious mind of the patient during the receptive period of childhood. These impressions were stored away in the unconscious mind and remained, as it were, inoperative until some potent exciting cause forced them above the plane of consciousnes. As an illustration of this very condition, I call to mind the singular history of a hysterical male patient of mine. He is a laboring man who had always enjoyed good health until he married one of three hysterical sisters, whose mother was also a victim of the same disease. About one year after his marriage he began to have nervous attacks, and soon developed major hysteria. My first impression was that it was a plain case of mimicry. But from a closer investigation I found that this man had been raised by an old maiden aunt who was a confirmed subject of hysteria. So my final solution of the case was that the hysterical impress was made on his unconscious mind during childhood by the constant example of the aunt, but that it remained quiescent until a powerful exciting cause, the hysterical paroxysms of his wife, to whom he was passionately devoted, forced it into an active conscious state.

All of our text-books record the fact that hysteria occurs more frequently among females than males. Some statisticians give the ratio of hysterical men to hysterical women of 1 to 20. Please bear this in mind. I have never seen a satisfactory reason given for the greater frequency of hysteria among females than males. If the majority of the subjects inherit the disease or the diathesis, what prevents the male from enjoying his part of the birthright? I would like to have a philosophical answer to this question. I am convinced that the male and female child inherit the diathesis in the same ratio, other things being equal. Is there any anatomical, physiological or embryological reason why they should not? If so, I hope some gentleman will give it in the discussion.

Why is it "that of hysterical women who have daughters, more than half transmit the disease to one or several of them, and again, that rather more than half of the daughters of the latter also become hysterical?" I believe it is usually due to imitation. The female child is kept almost constantly in the shadow of the hysterical mother. The male child is out with his play-fellows or in company with the father. What power could prevent the young daughter, who is the constant companion of the hysterical mother, from partaking of some of the joys and sorrows, and from unconsciously mimicking the contortions of the mothers' face and other actions while in a hysterical paroxysm? How many young daughters have failed to "get religion" when they heard the joyous hysterical exclamation of that beloved mother as she "came through" at a good old camp-meeting? The child is a creature of imitation like unto its distant relative, the anthropoid ape.

There is a family in our town with four genera-

tions of hysteria living under the same roof; great-grandmother, grandmother, daughter and granddaughter. It would require a superhuman power to prevent the little four-year-old granddaughter from becoming a confirmed subject of hysteria living in her present environment. A few evenings ago I was called to see a member of this family, and while there the grandmother seemed to be very much amused over a remark the granddaughter had made in regard to a slight attack of bronchitis from which she was just recovering. She made the remark innocently and seriously that "she felt very much like her grandmother, so nervous that she could not keep herself still and that she really believed she would die." How amusing to the grandmother! Little did she dream of the import of that remark, that this little girl had, unconsciously to everyone, taken her first lessons in imitating the hysterical phenomena of the grandmother. The unconscious psychic element in this child is receiving a most pernicious training.

All pathologists agree that no organic lesion has been found that accounts for hysteria. Most of the recent writers on the subject seem to be coming to the conclusion, as Dana expresses it, that "hysteria is essentially a psychosis." From the recent discoveries in regard to the physiology of the ductless glands, I believe that the pathology of the disease will be found somewhere in the "adrenal system." The many symptoms of major hysteria that resemble those diseases due to disorders of this body, leads me to believe that the pituitary gland has much to do with hysteria. Observe how closely the symptoms following disease or injury of the body of the sphenoid bone resemble some of those of hysteria. We have in acromegaly not a few symptoms in common with cases of major hysteria—anesthesia, general weakness, wandering pains, impaired vision, edema, polyuria and possibly others.

The treatment of hysteria has been just as unsatisfactory as that of cancer, or any other of the so-called incurable diseases. All of the anodynes, hypnotics, nervines and tonics of the pharmacopœia "have been weighed in the balance and found wanting." Harsh and cruel methods have been tried in vain, and to-day we are as much at sea in regard to the treatment of this vexatious disease as was Hippocrates. For centuries it was supposed to be entirely of uterine origin, as the name would indicate. This theory has been proven to be most absurd. But from the methods in use to-day among numerous general practitioners we would conclude that they still cling to "the faith once delivered by the Saints," the medical Priests of the Dark Ages, that the sexual organs surround a great central battery from which all hysterical currents are discharged. With the old bivalve vaginal speculum and the iodine cotton swab quite a few physicians of the present time are duping the poor women, deluding themselves, and in the end collecting some right handsome bills.

Hysteria is a psychosis and should be treated as such. To be sure, any complication should have attention, but hysteria proper should be treated psychically. It is an ideal disease, and as an eminent physician has said, if "ideal centers can produce ideal diseases, surely the rational cure is to first bring these ideal centers into a healthy condition and then make them the means of curing the ideal disease." The patients must have the very best mental, moral and social management. There should be a proper training of the will powers, by as many different methods as you have patients to treat. You can philosophize with some intelligent subjects as to how they can brace themselves to hold in abeyance the paroxysms, others may be cajoled and flattered, while a few demand the sternest and almost cruel treatment. The character of each individual must be closely studied.

To remove from the public the danger from the pernicious example of hysterical subjects is one of the most difficult problems to be solved by the alienist. How are we to prevent the children of the poor from associating with and imitating a case of hysteria in the family? The disease is found as frequently among the rich as among the poor.

The rich are able to send their afflicted on a sea voyage, to the various health resorts or to any institution that promises relief, but, like our Saviour said, "we have the poor with us always." One case of hysteria often ruins the happiness of the entire family, becomes a burden to a small community, a pest to the physician and a menace to society in general and childhood in particular. How to relieve this situation among the poor is a serious question. The most feasible plan that suggests itself would be to have homes or resorts where they could have all the necessary medical attention and be far removed from all anxious relatives and sympathizing friends, and at the same time their hysterical phenomena would be removed from infants and children. We have epileptic homes and leperous colonies; why not suitable resorts for the hysterical? Hysteria is far more prevalent than epilepsy, and under past methods about as rebellious to treatment. In many respects the life of an epileptic is preferable to that of the hysterical subject. Such afflicted poor certainly appeal most touchingly to the humanitarian and their deplorable condition and the far-reaching evil of their life to the community should be more prominently brought to the notice of philanthropists.

Summary.—1. We must look to the unconscious impressions of infancy and childhood for the etiology of hysteria.

2. The disease primarily is purely a psychosis.

3. The pathology, I believe, will be located in the adrenal system.

4. The treatment for hysteria *per se* should be psychical. Suitable resorts should be erected for properly treating and caring for the afflicted among the poor.

5. By such treatment, I believe, hysteria would soon be on the decrease instead of on the increase, as it has been for years.

ENLARGED BRONCHIAL GLANDS.

BY J. R. CLEMENS,
OF ST. LOUIS.

Enlarged bronchial glands, as met with in children, are noteworthy for three reasons: (1) Their great frequency; (2) the manner in which they are overlooked or ignored; (3) their potential toward tubercle and hence the danger of neglect.

In 70 consecutive cases in a children's clinic, where the children were brought up for various ailments, in 20 of these enlarged bronchial glands were found by me to be present. Hector Mackenzie, of the Brompton Hospital for Consumption, London, says the lymphatic glands, particularly in the young, have a special liability to infection by tubercle. In 897 cases of tuberculosis in children, which he has collected, the lymphatic glands were affected in 792, or in 88 per cent., rather more than seven-eighths of the whole. In his experience it is common to find caseous bronchial glands in cases of tuberculous meningitis and general miliary tuberculosis and it is certain that tuberculous disease of the lungs may be consecutive to tuberculous disease of the bronchial glands. Osler is equally insistent on the close connection that exists between tuberculous meningitis, miliary tuberculosis, phthisis pulmonalis and the parent seed of tubercle in the enlarged bronchial glands as met with in childhood. Walter Carr says: "In children who have died with tuberculous disease in any part of the body, the bronchial glands are usually affected and as statistics from the post-mortem rooms of the children's hospitals in London prove that fully one-third of the cases show evidence of tuberculosis, it is easy to see how common caseation of these glands must be. Out of 120 autopsies on children presenting tuberculous lesions the writer found caseation of the bronchial glands in 96 (80 per cent.) and a more careful examination of some of the remaining cases would probably have still further increased this number. Some observers state that caseation of the mesenteric is more frequent than of the bronchial glands but this certainly does not conform with the experience of the London Hospitals." I could go on indefinitely quoting equally pertinent extracts from authoritative sources to prove the sovereign importance of the early recognition of enlarged bronchial glands as met with in children, but the above will suffice.

It is strange that in some of the very latest text-books on diseases of children the subject of enlarged bronchial glands is either not touched upon or dismissed airily in a few words under the heading of Sequelæ of Whooping Cough, Measles, etc.

If ever there was an opportunity given us of exercising prophylactic measures against tubercle at its inception we surely have it in the beneficial control we can exert over it by an open-air life, sound food and the medicinal aids of iodide of iron and arsenic where we find enlarged bronchial glands in little children. This condition is often diagnosed as asthma, chronic whooping cough and the dyspneic condition of laryngismus stridulus when associated with the malformation of the thorax known as pigeon breast (the malformation being wrongly attributed to rachitis) but rarely if ever to its proper cause. Treatment is accordingly futile.

The most frequent history given by the mother is as follows: After some illness, two or three years previously, generally measles or whooping cough, the child has never been quite the same, remaining thin and weak and subject to a chronic cough.

The cough varies in intensity from a cough so slight that, but for its chronicity and the suggestion this conveys of tubercle, would not be noticed, to a cough, so violent and urgent, as to raise the suspicion of whooping cough in the minds of those ignorant of its chronicity. On examination of the child's chest after he has been undressed we will find on

Inspection.—An unwonted and prominent network of veins over the upper part of the sternum and thorax, deep blue in color and of large caliber.

Percussion.—On percussing across the chest from right to left dulness for a variable distance on either side of the sternal border will be noticed, the dulness being sometimes more extensive on the right than on the left and vice versa. Dulness will also occasionally be found in the interscapular region at the level of the fourth or fifth dorsal vertebræ. The dulness from above downward does not extend below the lower border of the manubrium.

Auscultation.—On hyperextension of the neck, so that the child's face may be in a plane horizontal with the ceiling while his body is in the upright position a bruit similar to the hum heard over the neck vessels in high grades of anemia will be met with, the retraction of the head tilting forward the lower end of the trachea and with it the glands, causing compression of the left innominate vein. Occasionally, due to pressure effects of the enlarged glands, we will meet with cases of cyanosis of the lips and face, spasmodic attacks of dyspnea and an increase in the anteroposterior diameter of the thorax due to atmospheric pressure and obstruction of the trachea. Sometimes there is a general recession of the soft parts of the chest wall with the resulting malformation known as "pigeon breast." Puffiness of the face will sometimes be found suggestive of renal disease. A very suggestive combination of conditions is (*a*) enlargement of the cutaneous veins over the upper part of the chest; (*b*) some deficiency of resonance over or on either side of the manubrium and (*c*) a venous hum in the same position when the head is retracted; especially if these occur in a thin, delicate-looking child, suffering from a cough for which no cause can be detected in the throat or lungs and from slight intermittent evening pyrexia without assignable cause. Brilliant results will reward our efforts if we bestir ourselves at once and we will have the satisfaction of knowing that we have cheated the great white plague of at least one victim.

A HUMBLE STERILIZER.

BY DOUGLAS H. STEWART, M.D.,
OF NEW YORK.

Although my experience with the very simple apparatus herein described is limited to efforts at procuring afebrile labors, yet its application may be extended to almost every emergency of domestic obstetrics and surgery.

The essentials are everyday articles, viz., an awl, a wash-boiler, a string, washing soda, water and a fire. Through the flange of the boiler cover, at each of the four rounded corners and at the sides, punch a hole, in such a manner that it will be closed in by the boiler rim when the cover is in place. Through each hole pass a string. To sterilize heavy bed linen, sheets, etc., make a criss-cross network over the fabrics after packing the cover in the inverted position: put your instruments in the boiler itself, cover them with six inches of water, add one heaping tablespoonful of washing soda, put on the cover, place the whole on a gas, kerosene or other stove and boil hard ten minutes. Then extinguish the flame or remove the apparatus from the fire and set it aside to cool.

There is a distinct germicidal advantage in commencing operations with cool water and in letting the lowering of temperature after sterilization take place quite gradually. When the cover is finally lifted, it is a sterile tray and should be stood bottom upward upon a convenient table, the strings should be severed, but its contents should be allowed to rest undisturbed until each is required.

In the absence of an awl the perforations may be easily made with the household shears.

Experiments have given thermo-metric readings of 100, 100⅕ and 101 on three successive trials. The instrument in use was a centigrade tested accurately in boiling water. It seems curious that temperatures above the boiling point of water can be obtained, but they can be.

A sheet was folded as compactly as possible enfolding the thermometer in "its midst" and both were carefully wrapped in a large linen towel. A cord bound the whole together in order to make the bundle as resistant to steam penetration as it possibly could be made under actual service conditions. It was quickly and easily demonstrated that the common pressure in the ordinary wash-boiler is sufficient to raise the temperature of its confined steam a full degree above the boiling point of water, *i.e.*, to 101° C. The liquid contents make an aseptic washing fluid, but one must keep vaseline and grease out of them when boiling.

A (P. and S.) student, who has been much interested in my "laundry work," suggests that "the punctures should be made through the descending perpendicular plate of the cover approximating its inferior border. Thus the water vapor may be more conserved."

I agree with his opinion in another matter, viz., "If some tired surgeon undertakes to clean oily instruments by a final boiling he will think of anarchy and dynamite." Boiled out water covered by a layer of oil may be raised to about 120° C., when it suddenly boils with almost explosive violence. Kitchen demonstration of this experiment is not desirable; a vacant lot furnishes more chances of escape.

121 West Eighty-eighth Street.

MEDICAL PROGRESS.

MEDICINE.

Temperature after Splenectomy.—A series of very interesting observations were afforded by a patient who developed a pneumonia several months after the spleen had been extirpated on account of the presence of a neoplasm. In reporting the case, W. v. Moraczewski (Berl. klin. Woch., Nov. 2, 1903) shows that aside from the changes in the blood, the course of the temperature did not vary from that in a normal person. The phenomenon most worthy of note was the connection between the increase in the blood cells and the excretion of phosphorus in the urine. The maximum amount of phosphates was excreted during the period when the leucocytes were least in number. As the latter became more numerous, the percentage of phosphates became gradually reduced and remained so until the leucocytes reached 33,000 in number, when the phosphate excretion again reached the normal figure. At the same time there was a marked increase in the quantity of calcium salts excreted, and there was a sudden drop to the normal as soon as the leucocytes reached a normal number. The potassium salts varied in a manner similar to that of the phosphates. The author assumes that the reduction in the potassium and phosphate salts is due to their increased consumption by the growing white cells.

Value of Pentose as Food.—It has frequently been pointed out that pentose may be destined to play an important part as food, since it can be easily and cheaply manufactured from such waste-products as straw and sawdust. Former observations made it seem as if assimulation were particularly active during monition, but E. Bendix and K. Dredger (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 1 and 2) arrive at different conclusions. Examination of the urine showed that about two-thirds of the sugar is used up normally, but exactly the same figures were obtained with the same amount ingested after a period of fasting up to the appearance of acetone and diacetic acid in the urine. The conditions in chronic inanition may, however, be different than in acute hunger, and it is also desirable to experiment with different varieties of pentose, such as rhamnose and arabinose.

Studies upon Nephritis.—In a case of subacute nephritis, F. Erben (Zeitsch. f. klin. Med., Vol. 50, Nos. 5 and 6) found the number of red and white cells nearly normal. The variations present were chiefly of a chemical nature, thus the albumin was considerably diminished in the plasma, the globulin slightly increased, cholesterin and water and alcohol-soluble extractives diminished in both cells and plasma, phosphate and magnesia subnormal and lime above normal in the plasma-ash, while the cell ash was normal. In chronic parenchymatous nephritis almost all the albumin in the serum was substituted by globulin with an increase of fibrin; the other changes were similar to those of subacute nephritis. In secondary contracted kidney, with amyloid degeneration, the globulin was also reduced, the fibrin increased, cholesterin and alcoholic extract diminished in the erythrocytes and increased in the serum, phosphates and potassium diminished, and sodium chloride

increased in both. In conclusion, the character of the albumin excreted by the kidneys was studied. The albumin itself did not correspond to the ingested albumin, but to cellular albumin, and the same was true of the globulin, though the large amount of this substance in the serum made it seem more probable that it was a pathological product excreted by the kidneys.

Delirium Cordis.—Six cases of rapid, arrhythmic heart-action coming on in attacks, have been observed by A. Hoffmann (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 1 and 2), who applies the name delirium cordis to this condition. The age of the patients varied from nine to fifty-eight years, the inciting cause which led to an attack was bodily exertion, excitement, or the excessive use of alcohol or tobacco. The heart may beat as fast as 300 times a minute; on examination there is no dilatation, the first and second sounds are very much alike, and murmurs are usually not heard. Slight irregularities are common, thus there may be an alternating pulse or a beat is dropped occasionally. Blood-pressure before, during and after the attack shows only slight change, the urine is often increased in quantity, and of low specific gravity, but free from albumin and sugar. Gastric and intestinal symptoms, fever, neuralgia and variations in the size of the pupils do not belong to the symptom-complex. A strange sign is the mobility of the apex; in all cases it moved 5 to 9 cm. outward when the left lateral position was assumed. The subjective symptoms usually only amount to a sensation of discomfort sometimes increased to pain, but the bodily functions hardly ever suffer. The prognosis is excellent. In some cases the attacks will cease at once if the patients lie down and breathe deeply or hold their breath in deep inspiration; in others, pressure on the vagus or stooping-down may be effectual. Alcohol, tobacco and severe exertion should be forbidden.

Influence of Environment on the Development of Tuberculosis.—By carefully studying the social condition of the patients of his dispensary, E. Schwarzkopf (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 1 and 2) could prove that constant contact with unclean tuberculous patients undoubtedly favors infection, even in those who are not otherwise predisposed. Almost every individual inhales virulent bacilli occasionally, but a rapidly repeated infection will overcome the natural barrier of persons with strong lungs. The danger thus stands in direct proportion to the number of patients in the neighborhood, and the duration of exposure. It is greatest between the fourteenth and fortieth years, and increases steadily up to the fortieth year. If tuberculous patients are sanitary in their habits, very little risk is incurred. In women, lactation and pregnancy are two important predisposing factors.

Experimental Fat Necrosis.—It is now considered settled that fat-necrosis is caused by the fat-splitting ferment of the pancreas, and that this fat necrosis is responsible for the necrosis of pancreatic tissue. As soon as the pancreatic juice comes into contact with the intra-pancreatic fatty tissue, the fat will be converted into soluble soap, which is soon changed into unsoluble soap by combining with the lime of blood and tissues. The etiology of cases of so-called apoplexy of the pancreas has long been obscure, but a very satisfactory explanation is given by O. Hess (Münch. med. Woch., Nov. 3, 1903). This writer finds that if a sufficient amount of fat is injected into the excretory duct of the pancreas, total necrosis of this organ, fat necrosis and hemorrhage ending in death will follow. The symptoms correspond to those of apoplexy in every way. The same results were obtained with sodium soap, but glycerin, paraffin oil and starch-paste proved absolutely harmless. The frequent combination of fat necrosis with cholelithiasis makes it probable that the common bile duct is dilated by former gall-stones, thus permitting the fatty contents of the duodenum to enter the pancreatic duct where lesions similar to those obtained in the animal experiments are set up. Why death should be so sudden is not quite clear, but it is possible that an acute soap intoxication is responsible.

Some Rare Auscultatory Findings.—The Flint murmur at the apex has been observed repeatedly by L. Syllaba (Zeitsch. f. klin. Med., Vol. 50, Nos. 5 and 6), and is not considered by him of such rare occurrence. It varies considerably in strength in each case, and may even disappear for a time. A mitral stenosis may thus be diagnosed on one occasion and an aortic insufficiency on another. In doubtful cases the diagnosis can generally be cleared up by giving digitalis when the murmur and fremissement disappear. The murmur is best explained by an inversion of the aortic flap of the mitral valve, due to the regurgitation of the blood, so that the orifice is narrowed. The prognosis is not more serious, though the patients often suffer more than uncomplicated cases. In a number of patients of advanced years the author discovered a systolic murmur at the apex without evidences of endocarditis, but instead, an arteriosclerosis or nephritis. The murmur may be functional and inconstant, or organic and permanent; in the former case there is irregular action of the papillary muscles or dilatation of the ventricle; in the latter, an extension of the sclerotic process upon the valve. A gallop rhythm frequently complicates the condition. It may be very difficult to decide in such cases between endocarditis, with congestion of the kidneys, and nephritis, with involvement of the heart, but a conclusion can often be arrived at by the condition of pulse, urine and blood-pressure, the size of the heart, the strength of the second sounds over aorta and pulmonary artery and the history. Another interesting lesion is the relative insufficiency of the aortic valves found in old people owing to arteriosclerotic shrinkage of the valves or dilatation of the beginning of the aorta. The clinical symptoms are those of an aortic insufficiency, but the murmur is somewhat different; it is postdiastolic and very short and feeble. These patients frequently die suddenly of syncope. Sometimes only one of the three flaps is retracted, at other times there is only a relative insufficiency, and then the murmur is liable to be inconstant. A murmur of little significance is sometimes heard in old, healthy people during the second half of inspiration over the upper portion of the sternum. It is rough and consists of two or three separate sounds, each synchronous with cardiac systole. A roughening of the adventitia of the large vessels at their origin is assumed, but as yet no autopsy findings have borne out this view. Pseudopericardial murmurs may be due to extrapericardial pleurisy, they are rough, heard best along the left margin of the lung, and are synchronous both with respiration and cardiac action. With forced respiration, they impose as pleural, with superficial respiration as pericardial sounds. A second group is less common and depends on serofibrinous perihepatitis, and a third upon right mediastinal pleuritis. These latter cases do not make the impression of being very ill, and the murmurs resemble those of insufficiency and stenosis of the aorta, but do not replace the normal sounds, and are clearly influenced by respiration, though they do not disappear entirely when the patient stops breathing. In severe chlorosis, venous hums sometimes impose as murmurs of aortic stenosis and insufficiency, since they may become louder with every systole. They can, however, be traced upward along the right jugular vein, where they become continuous. Closely allied are certain diastolic sounds sometimes heard over the pulmonic

vein in pernicious anemia. Cardiopneumatic sounds are due to an aspiration of air during every cardiac movement into that part of the lung lying upon the heart. The patients are generally neurasthenics, and much excited during examination; the murmur is heard over the third or fourth left interspace, and is most often systolic in tune. The character of the sound is characteristic and unmistakable.

SURGERY.

Selection of Anesthetic for Children.—Although chloroform is considered to be more dangerous than ether in adults its use in children has been very generally recommended because of the belief that children were practically immune to the bad effects of chloroform. S. J. Kopetzky (Med. Rec., Oct. 3, 1903) believes that chloroform is dangerous because an overdose may be too easily given and his contentions are borne out by many men who have had occasion to give it in a large number of cases. Cardiac failure may set in at the very beginning of the anesthesia, because of the violent and dangerous struggle which takes place in frightened children. Death occurs suddenly and without warning. The tendency to push the anesthetic is too tempting especially when the patient is afraid and struggling. Cardiac syncope following vomiting may occur at any time during or after the administration of chloroform and result fatally. He particularly warns against the practice of beginning operation before complete anesthesia and also against the use of chloroform in the upright position.

Intestinal Anastomosis by the Elastic Ligature.—The application of the elastic ligature as a means of producing an intestinal anastomosis is a very simple procedure says T. A. McGraw (Am. Gyn., Sept., 1903). The two viscera are brought together and the surgeon connects them with a single line of Lembert sutures a little longer than the desired opening. The rubber cord is then by means of a large needle, passed through the wall of first one and then the other bowel and tied firmly with a single knot. Before tying it, however, a silk thread is laid under the knot, and, after the knot has been firmly tied with the rubber stretched to its uttermost, the silk thread is made to fasten it in place. Both threads are then cut short and the Lembert suture is now completed so as to form a ring to enclose the suture of rubber. In passing the rubber through the gut it should be put on the stretch in order to lessen the size, and drawn slowly and carefully through in order not to tear the gut. The advantages of the procedure are (1) its simplicity and quickness of application; (2) its aseptic quality, for the rubber fills the openings through which it passes so completely that no extravasation is possible; (3) the delay in opening the passage until the intestines have become well glued together; and fourth, the ability to make with it a communication of any desired length. Compared with the Murphy button it is less liable to meet with disaster from faulty technic, causes no loss of blood, is more aseptic and it leaves no foreign body in the bowel.

Thyroid Fistulæ.—An interesting and complete study of this subject has been made by E. Payr (Archiv f. klin. Chir., Vol. 71, No. 2), from which he concludes that fistulæ following goiter are comparatively rare when the large number of other diseases of the thyroid gland are considered. Under certain circumstances any factor which produces a strumitis or a thyroiditis may also result in the formation of a goiter fistula and in exceptional instances it may be caused by parasites or neoplasms of the thyroid. Among the conditions which interfere with the closure of a fistula in this locality are tissue necroses after infectious processes, chalky concretions in the cavity, and calcification or sclerosis of the walls; in the latter case the insufficient vascular supply does not permit of the ready growth of granulation tissue. He divides these fistulæ into internal and external, the latter being extremely rare. The diagnosis is especially difficult where the diseased thyroid occupies a retrosternal position, or where there is an accessory thyroid. In such cases probing combined with the use of the X-rays may prove an efficient help. Treatment should consist in all cases of fistulæ following strumitis, on account of the dangerous complications, of complete extirpation, together with the focus of the disease and the lobe of the gland which is involved.

Hyperesthesia in Appendicitis.—A phase of appendicitis which has hitherto been neglected is the behavior of the skin toward sensation. A noteworthy fact has been brought out by J. Peiser (Münch. med. Woch., Oct. 13, 1903), namely that in the majority of cases sensibility is reduced in the right iliac region in an ill-defined area which does not admit of any characteristic figures. In one case there was hyperesthesia and in another, this developed later. The writer recommends increased observation on this phenomenon as its constancy and its relation to the pathological condition of the appendix may aid in diagnosing obscure cases.

Disadvantages of the Trendelenburg Position.—The few objections already advanced have been added to by P. Kraske (Archiv f. klin. Chir., Vol. 71, No. 2) as the results of personal experience. He does not wish to decry the procedure and admits its great value in many cases, but advises caution in certain patients. Among these are individuals who present a weakened condition of the heart muscle as the result of degenerative changes. Here the overdistention of the heart and the increased pressure of the column of blood in the inferior vena cava, may lead to an acute irreparable cardiac dilatation. In cases where there is an extensive deposit of adipose tissue in the omentum, the mesentery and the appendices epiploicæ, a permanent displacement of the intestines may take place, resulting perhaps in intestinal occlusion. Possibly under such circumstances the pressure of the weighted intestines against the under surface of the liver may produce congestion in the portal vein and its branches and also congestion and hemorrhages in the gastric mucosa. He believes that this fact affords an explanation of those cases where gastric hemorrhages have been observed soon after operation. In corpulent persons the author advises limiting the Trendelenburg position to as brief a time as possible. After the operation is completed the patient should then be placed in an elevated position for a time and all compressing abdominal bandages avoided.

Improved Narcosis.—There is a decided advantage in using a mixture of chloroform and ether instead of either pure drug as the dangers of pneumonia and cardiac paralysis are much minimized. P. Krönig (Münch. med. Woch., Oct. 20, 1903) finds, however, that it often requires fifteen to thirty minutes before anesthesia is sufficiently deep for laparotomy. He has, therefore, constructed an apparatus similar to a Bennet inhaler with which narcosis may be begun with laughing gas and then continued with ether and chloroform. The operation can usually be begun in four to five minutes and accidents were never observed.

Blood Examinations in Abdominal Diseases.—Probably leucocytosis instead of being an absolute and infallible indication of the presence of pus, is a sign of very great value of the existence of toxemia. C. J. N. Longridge (Lancet, Oct. 24, 1903) reaches these conclusions from a study of a large number of cases at St. George's Hospital. He believes that it is not possible

at present to fix any definite relationship between the amount of the leucocytosis and the intensity of the toxemia, but the broad fact remains that an increasing leucocytosis is the most scientific and accurate measure for gauging the increased virulence of an appendicular or kindred infection. On the other hand, a decreasing leucocytosis is an evidence of decreasing virulence or walling off of the toxic products. He agrees with DaCosta that the blood count in appendicitis is not a pathognomonic sign, but that it is of value for routine clinical surgery.

Perforation of the Colon by Small Foreign Bodies.—The list of materials grouped under this term—foreign body—is much broader than is usually realized. Many of them are metallic, derived from the metal instruments employed in preparing food, or from the pans and pots used in cooking it. Fragments of bone from the smaller vertebrates are frequently indigested and passed into the colon. These types of foreign bodies are more known than those accidentally swallowed and usually considered as such. J. Bland Sutton (Lancet, Oct. 24, 1903) states that this may be of profound surgical importance, especially when the perforations are in close relation to an epiploic appendage. Needless to state that the vast proportion of those ingested are as easily egested, but the frequency of anal abscess serves to show that a small proportion at any rate does not make so fortuitous an exit. The appendix epiploica is anatomically a fold of peritoneum filled with fat, its size depending on the amount of fat. It is easy to show that the serus investment of the colon reposes on a subserous tissue containing varying proportions of fat throughout that part of the circumference of the gut which receives the peritoneal investment. It is thus clear that there are portions of the circumference of the colon where a sharp foreign body could penetrate and escape into the general peritoneal cavity, and the thinner the person, the greater the arc of the gut which would allow this form of penetration. In a fat person, on the other hand, there is a far greater extent of its circumference so protected by fat, into which the escaping body would be more probable to find its way and occasionally lodge in the appendix epiploica. The fatter the patient, the less likely is the foreign body to penetrate the general cavity, and the greater the chance of epiploic involvement. It is conservative to state that in some instances at least the cause of the tumors of the abdomen which disappear spontaneously after operation is a minute foreign body which has perforated the cecum, the colon, the sigmoid or the rectum. The manipulation of the parts at the time of operation serves to dislodge the foreign body and admit of evacuation and disappearance of the tumor. Thus Bland Sutton explains some of the perplexities of spontaneous disappearance of solid abdominal tumors often supposed to be malignant, in which the patient has lived to mock his advisors.

New Method of Intestinal Union.—Mayo-Robson in his masterly work upon the intestines, has left a markedly favorable predisposition in the mind of the British surgeon toward the "bobbin." Alexander McLenan (Lancet, Oct. 24, 1903) introduces his article by showing two microphotographs which are intended to compare his method with the results obtained by the Czerney-Lembert technic. The latter shows in a marked degree the annular shelving stricture, which is gratifyingly absent from the "bobbin" and ring anastomosis. The bobbins, some of which have been made of formalin—hardened gelatin rather than decalcified bone—are slightly conical. This is of distinct advantage, because when inserted, the small end of the cone is placed toward the stomach and therefore it is very unlikely that particles of food, which have once entered, will lodge in the canal. After the bobbin is placed in situ, a light umbrella ring is slipped over it to hold the gut in place. Sutures may be put in at the junction of the peritoneal surfaces, but are not to be recommended, as they lead to adhesions.

Diagnosis of Tuberculosis in Bones and Joints.—By means of an extensive series of X-ray pictures of the knee-joint, K. Ludloff (Archiv. f. klin. Chir., Vol. 71, No. 3) has compiled a number of rules by which he believes that the diseased can be differentiated from the well joint. These pictures are taken in two directions—from before backward, and from the side. The characteristic points in a tuberculous knee are (1) the diminution and finally the disappearance of the protuberances at the line of junction of the bone and cartilage, especially at the internal condyle, up to the fifth year, and the presence of rough surfaces at this junction up to the seventh year; (2) new bone formation in the shape of small conical projections on the under surface of the condyles; (3) enlargement of the ossified parts of the condyles, the patella, the tibia and the head of the fibula—appearing as if dilated; (4) enlargement of the epiphyseal center and its more ready permeability by the X-ray. These appearances are no doubt caused by the localization of the tuberculous process near the junction between the bone and cartilage in the region of the ossification center of the internal condyle. It is impossible to say, however, whether this is the primary focus of the disease.

Antiseptic Wound Dressings.—The value of the dry and moist dressings on a wound has been made the subject of animal experiments by W. Noetzel (Archiv f. klin. Chir., Vol. 71, No. 1), in order to determine their relative merits. It was found that a dry, as well as moist gauze dressing (which was allowed to dry) was able to absorb tetanus bacilli placed on a muscle wound in a rabbit in such a thorough manner that the animal did not become infected with the disease. The more marked capillary drainage present in the moist dressings is shown by the fact that the bacilli penetrated the outermost layers of the latter, whereas only the inner layers of the dry dressing contained bacilli. Gauze moistened with bichloride solution was found to have inhibited the growth not only of the tetanus germs, but also those which had been derived from the surrounding skin. Eczema due to the sublimate gauze is not as frequent a complication according to this author. In order to be certain of avoiding it he recommends painting the vicinity of the wound with dermatol made into a paste with sterile water.

Operative Interference in Gun-shot Wounds of the Abdominal Cavity.—It is the opinion of the majority of surgeons that gun-shot wounds require operative interference, and expectant treatment has in the majority of cases been followed by fatal, or at least untoward results. B. K. Tinkelstein (Roussky Vrach, Sept. 27, 1903) bases his article on the results obtained in six cases, four of which were operated on. In the first case a man of twenty years received a pistol wound in the abdomen. As operation was refused and patient felt comparatively well, he was given morphine, ice on the abdomen, and an aseptic bandage applied. On the next day, however, there was vomiting (twice), pain at the point of entrance of the bullet, tenderness of the abdomen, pulse 120, and temperature 38.5° F. The condition became worse the following day, the abdomen became extremely painful, pulse normal; fatal issue at midnight. In this case the bullet entered under the lower border of the right kidney, penetrated through both walls of the intestine, while the peritoneum showed general inflammation. In the second case the point of entrance

was three fingers below the unbilicus, and two to the left of the median line. Immediate laparotomy was performed, and the peritoneum was found to have been penetrated by the bullet. Two intestinal wounds were detected and closed by Czerny-Lambert sutures. The bullet could not be found. Recovery uneventful. A somewhat similar case, though of greater severity, was operated on with similar favorable results. The other cases are of the same character, except the sixth, in which no operation could be performed, with the result that the patient died; and this, notwithstanding the fact that in both the first and the sixth case the author had to do with young people, of good general condition, who were given the best possible medical attendance; besides the involvement of the peritoneum was apparently not sufficiently extensive or severe to cause death; and it is quite probable that operative interference would have saved both patients. The favorable issue following operation is especially important in two of the cases, where there were multiple wounds of the intestines and the mesentery; and the author entertains no doubt as to certainty of death in both cases, if not for his interference. The bullet was not found in either of the cases, having probably become embedded in the muscles of the spine. In one case in which the stomach was severely injured operation failed to save the patient. We must, however, add that in this case both the liver and the pancreas were wounded, and death was due to a severe peritonitis.

Aneurism of the Hepatic Artery Treated by Ligation.—H. Kehr (Münch. med. Woch., Oct. 27, 1903) reviews the literature of hepatic aneurism, and finds that of the 22 cases published, only 3 were treated surgically. Since these were all fatal, his case is the first successful one on record. The symptoms were those of cholelithiasis, with gastric or duodenal ulcer, since the aneurism had ruptured into the gall-bladder from where the blood found its way into the stomach and intestines. The patient was anemic and in very bad condition, but his life was probably saved by a firm clot which had formed in the cystic duct and which was probably responsible for the attacks of colic. A pulsating tumor could not be felt through the abdominal walls. The operation was rendered difficult by an enormous hemorrhage. After the ligature had been applied, the sac was freely incised and proved to be the size of a goose egg. Owing to the large number of collaterals which had formed during the two years the patient had been complaining, the outcome was favorable. The cause of the aneurism was entirely obscure in this case, since there was no history of lues, arteriosclerosis, cholelithiasis or trauma. Where the sac ruptures into the abdominal cavity, death is so sudden that an aneurism is often not suspected, but in other cases, a diagnosis will often be possible. The occurrence of a marked anemia and of hematemesis and intestinal hemorrhage, accompanied by biliary colic and jaundice, is highly suggestive. It may be possible to fill the gall-bladder, but the aneurism is generally seated too deeply to be palpated. It must not be forgotten, however, that gastric hemorrhages may also occur in cholelithiasis, due to the general cholemic diathesis, acute portal thrombosis or ulceration of stomach or intestine. Conversely, a duodenal ulcer may be complicated by cholelithiasis, owing to kinking of the cystic duct, from periduodenal adhesions. The only rational treatment for aneurism can be ligation, for though physiologists state that the hepatic artery is indispensable for the nourishment of the liver and its vessels, sufficient collaterals have generally formed to prevent a necrosis. If the aneurism involves only one branch, this alone should be tied, especially since it is comparatively easy to isolate the artery. The sac should be tamponed with sterile gauze and the gall-bladder may be removed.

PHYSIOLOGY.

Subcutaneous Nutrition.—For the purpose of determining whether certain albuminoid substances could be injected subcutaneously, without the unpleasant sequelæ attending the injection of the ordinary albumin or albumoses (peptones), a series of animal experiments have been undertaken by Trolldenier (Berl. klin. Woch., Oct. 5, 1903). The albumin was in solution and in the form of an intermediate product between true albumin and the ordinary commercial peptone. It was assumed that the more nearly the material approached the natural, unchanged albumin, the more readily could it be employed to furnish a substitute for the albumin in the body. The experiments were made in dogs, a 10-per-cent. solution of the material being injected subcutaneously, in doses of from 50 to 100 c.c., under strict aseptic precautions. These experiments showed that the albumin was not excreted with the urine and the dog in sixteen days increased 0.5 kgr. in weight. The only difficulty seemed to be the development of painful abscesses at the site of injection, due to the slow absorption of the material injected. These, however, healed readily, and did not interfere with the good condition of the animal. Further experiments were made until a solution was finally obtained, which contained 8 per cent. of the intermediate products mentioned, and also 0.6 per cent. of cooking salt. This was also employed in two human subjects, and a number of dogs with much better success, causing only a slight swelling which soon subsided.

Physiology of the Pineal Gland.—In a previous investigation of the functions of the hypophysis, E. v. Cyon (Pflüger's Archiv, Vol. 98, Nos. 7 and 8) believed that the pineal gland shared with the hypophysis the power of mechanically regulating the quantity of cerebrospinal fluid in the ventricles of the brain. In order to make a complete study of the chemical, as well as the mechanical aspects of the subject, the author first experimented with extracts of the pineal body. The intravenous injection of large doses of the latter diminish the rate and increase the force of the heart-beat, and cause the appearance of the irregularities known as the bigeminus and trigeminus pulses. These changes depend on stimulation of the central ends of the vagus. The question arose whether these changes represent physiological actions of the pineal gland or are to be attributed to the action of the inorganic substances that are found in large quantity in the pineal body under the form of concrements. The author finds that there is no ground to suppose that the pineal extracts are an exception to the other extracts that act favorably upon the heart and blood-vessels. A series of experiments were made directly upon the gland itself. The lightest contact of electrode connected with an inductorium having a current of 5 volts in the primary coil, produced a slight change in the form of the gland. This change consisted in a shrinking of the glandular tissues with a slight shifting of the gland as a whole. What is the physiological significance of these changes? The situation of the pineal gland in the path of the aqueductus sylvii, near the mouth of the third ventricle, suggested the hypothesis that a contraction accompanied by a shifting of the gland, would serve to regulate the flow of cerebrospinal fluid to and from the third ventricle. The pineal gland would, therefore, play a mechanical rôle, controlling the flow of cerebrospinal fluid in the aqueductus sylvii, and according to the pressure imparted thereby to the fluid in the third ventricle,

to cause a dilatation or contraction of this cavity. This hypothesis is strengthened by the discovery made by N. Nicolas that the pineal gland contains striated muscle fiber. The fact that animals from which the hypophysis has been carefully removed, and human beings suffering from tumors of the hypophysis, soon succumb with manifestations of increased intercranial pressure (coma, vapor, etc.), seem to indicate the mechanism of the pineal body is entirely depending for its perfection upon that of the hypophysis, or that the latter is not alone capable of fully warding off excessive intercranial pressure.

Anatomico-physiological Significance of the Muscularis Mucosæ.—The interesting fact was established by A Exner, according to Bianca Bienenfeld (Pflüger's Archiv, Vol. 98, Nos. 7 and 8), that the muscularis mucosæ of the intestinal canal prevents the entrance of foreign bodies into the mucous membrane. It is indeed very remarkable that frequently sharp foreign bodies pass through the alimentary canal without causing any wounds, in spite of the fact that with certain animals, as with beasts and birds of prey, the repeated swallowing of sharp bones is a daily occurrence. In a series of comparative anatomical researches the author, a student of medicine, found that the muscularis mucosæ of the stomach and of the upper part of the small intestine is much more distinctly developed in animals, whose alimentary canal is exposed to injury from sharp foreign bodies, than in those feeding upon a soft kind of food. In the lower part of the small intestine and in the large intestine, this thickening—a species of compensatory hypertrophy—is not evident. In general, the muscularis mucosæ decreases in thickness from the stomach to the large intestine. This is to be attributed to the fact that sharp bodies, such as fish-grates, in their course through the alimentary canal, are partly softened and blunted by the digestive secretions, and are also enclosed in firm scybala.

Influence of Bodily Exercise upon the Healthy Pulse-rate.—A large number of determinations of the frequency of the pulse made upon individuals in good health after certain forms of exercise, by F. Tewildt (Pflüger's Archiv, Vol. 98, Nos. 7 and 8), show that the acceleration is not so much dependent upon the duration of exercise as upon the speed with which it is performed. A moderate but long-continued exercise increases the frequency of the heart-beat to a much less degree than a series of movements very rapidly performed, which may at times double the frequency of the pulse. Daily observation shows that this law does not hold with cases whose circulatory apparatus is no longer intact, in whom excessive exercise may cause irreparable damage, not seldom resulting in death.

Rôle of Pancreas and Muscle in Burning Carbohydrates.—It is now known that the burning of large quantities of grape-sugar in the muscles, is brought about by the action of a ferment, according to O. Cohnheim (Hoppe-Seyler's Zeitsch., Sept. 3, 1903). Moreover, the discovery of pancreas-diabetes has indicated that in the higher animals the pancreas plays a decisive rôle in the metabolism of sugar. It secretes a substance whose absence from the blood renders the oxidation of sugar impossible. The search for a glycolytic ferment in the pancreas has not yet been rewarded with success. The author sought to combine both organs, namely, muscle and pancreas, and to prove whether they cooperate to produce a glycolytic ferment. This he found to be the case. From admixture of muscle and pancreas, a non-cellular fluid may be obtained, which, in the presence of grape-sugar, changes it so that it loses its reducing power. The two organs separately cannot do this. It would, therefore, appear that in order that grape-sugar may be oxidized in the organism, the cooperation of muscle and pancreas is necessary. Since the catabolism of sugar takes place in a homogeneous fluid outside of the cells, it must be the result of some ferment-action. This process may be analogous, either with the fact discovered by Ehrlich that for the accomplishment of lysin-action, complement and intermediate body are necessary, or with the condition discovered by Pawlow, namely, that the trypsinogen of the pancreas is made active only by the enterokinase secreted by the intestinal mucosa. The teleology of such a cooperation can easily be explained. The burning of sugar must take place in the muscles, since in them the resulting energy is utilized. But in the fluid contents of the muscle, the glycolytic enzyme cannot be separated from the sugar. Hence a provision must be had for making the enzyme active only when the energy is demanded. This provision is furnished by the internal secretion of the pancreas.

Reverse Action of Proteolytic Enzymes.—In 1895 itwas discovered, according to R. O. Herzog (Hoppe-Seyler's Zeitsch., Sept. 3, 1903), that the addition of pepsin, trypsin or papayotin to concentrated solutions of albumoses, caused the formation of a flocculent or jelly-like precipitate. This phenomenon was termed plastein-formation. The recent experimental proofs of the synthetic powers of ferments suggest that the formation of plastein is also to be considered the result of a synthesis of the split products of proteolytic ferments. The question arose whether the substance "pepsin" is not a mixture of the ordinary peptic enzyme and one that results in the formation of plastein. The author, by means of a series of physicochemical researches, has proved that the proteolytic enzymes are indeed capable of a reverse action. Recently E. J. Spriggs has shown that during the course of the peptic digestion of albumen, the viscosity of the latter diminishes at first rapidly and later slowly. The author finds that in the presence of the proteolytic enzymes, concentrated solutions of albuminoses increase in viscosity. In this connection it is necessary to refer to the interesting fact discovered last year by Weinland, namely, that the juices expressed from intestinal worms, such as *Ascaris lumbricoides*, contain an antiferment, counteracting the action of pepsin. This, of course, protects the parasite from proteolytic dissolution. The author used this phenomenon as a test of the reversionary power of the proteolytic ferments, for if the splitting and the synthetic action of the latter enzymes be attributed to the same cause, then any agent, such as the antiferment of *Ascaris*, that inhibits the one would also inhibit the other function. This is found to be the case. The increase of viscosity above mentioned is inhibited by the addition of the juice of *Ascaris* and, indeed, to the same degree as the viscosity is reduced during the hydrolytic action of the ferments. This regular increasing viscosity is considered by the author as a proof of the reversion hypothesis.

Physiological Relations of Glycerin.—This substance is found normally in the blood in very small quantities, according to M. Nicloux (Jour. de Physiol. et de Path. Gén., Oct. 15, 1903). This quantity is not influenced by the condition of fasting nor by a diet rich in fats. After the intravenous injection of glycerin this substance is rapidly excreted in the urine. It appears that the renal epitheluim exerts a powerful selective action on glycerin.

The Iron-content of the Animal Body.—A new determination of the iron-content in the various tissues was made by M. Schmey (Hoppe-Seyler's Zeitsch., Sept. 3, 1903), with certain interesting results. A review of the classical investigations on the proportion of iron in

the various foodstuffs reveals the fact that of all nutrients, the more important ones have a larger iron-content than milk. A priori, the opposite would have been expected, inasmuch as milk forms at first the only nourishment for the growing animal, which, for the building up of the iron-holding organs and tissues, requires more iron than the adult animal. The paucity of the quantity of iron in milk is all the more surprising, inasmuch as all the other inorganic constituents are present in this medium in exactly the same proportion as they are required by the nursling; but the latter requires only one-sixth of the amount of each of these inorganic constituents furnished. All the rest is wasted. In the case of iron, this extravagant expenditure on the part of the maternal organism is not found. The solution of this apparent contradiction is found in the fact that at birth the nursling possesses in store for future use a large supply of iron. In fact, the amount of iron in the entire organism is proportionately greatest at birth, and gradually decreases with the growth of the animal. The microchemical researches of Macallum have shown that ingested iron is absorbed by the epithelium of the small intestine. Abderhalden proved that a diet containing an excess of inorganic and organic iron, causes a deposition of this substance in the duodenum, in the rest of the small intestine in the solitary follicles and Peyer's patches, and next in order, in the cecum, large intestine, mesenteric nodes, liver, spleen, and least of all, in the muscles. The question arose in the author's mind, whether other organs possess this capacity for storing up iron, particularly the muscles, which by virtue of their great total bulk, may store up a large quantity of this element. He finds that this is really the case, and also that the cardiac muscle is, without exception, richer in iron than the rest of the musculature.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Origin of the Alexines.—A series of researches in the factors that lie at the base of natural immunity, was made by R. Turro (Journal de Physiol. et de Pathol. Gén., Sept. 15, 1903), with the following results: The alexines are substances that act upon the bacterial protoplasm, dissolving it or changing it into an amorphous material. To this process may be given the name bacteriolysis. The alexines originate in the cellular plasmas; those that are furnished by the phagocytes and the macrophages, are called cystases. The properties of the alexines vary according to the source. Some are active and others inactive, with respect to particular bacteria. Chemically considered, the alexines are enzymes that digest the bacteria by means of a progressive hydrolysis. This conception indicates the powerful means by which the organism protects itself against infection. The cellular juices are capable of elaborating an almost inexhaustible quantity of alexines. An alexine obtained from the spleen is capable of digesting 20 to 30 times its weight of the *Bacillus anthracis*. These enzymes may remain potential or inactive, if there are no adequate means for their solution and diffusion in the blood and lymph. The discovery of the intimate mechanism by means of which the alexines are formed and acquire the expansive force which distributes them easily throughout the body, will furnish the solution of the problem of natural immunity, whose process is intimately bound up with the nutrition of the cell, under its double aspect of assimilation and disassimilation.

Disseminated Diphtheritic Gangrene of the Skin.—In the case of a male adult not primarily suffering from diphtheritic angina, R. Bernard and O. Jacob (Arch. de Méd. Expér., Sept., 1903), observed the condition of disseminated cutaneous gangrene. This proved to be, on microscopic examination, a condition caused by the bacillus of Loeffler, probably aided by a polymicrobic symbiosis. From the clinical standpoint one may consider that disseminated cutaneous gangrene is an atypical form of diphtheria, having no peculiar symptomatology, and whose diagnosis is a bacteriological one. In the case reported, the repeated injections of the antitoxic serum were followed by a cure.

Typhoid Fever and a Diplococcus.—In the course of and during the convalescence from certain cases of typhoid fever, there have been observed by H. Leroux and M. Lorrain (Arch. de Méd. Expér., Sept., 1903), certain serious complications, characterized by vomiting and polymorphic erythemas, of an epidemic character. These accidents are not caused by the typhoid bacillus, but are the result of an additional infection, whose pathogenic agent in the cases observed, appears to be a diplococcus analogous to the *Diplococcus hemophilus* described by Deguy in metadiphtheritic infections, and resembling in certain features the enterococcus of Thiercelin.

Toxic Power of Blood Serum.—The blood serum of the deer was used in a series of experiments by A. Sclavo (Archives Ital. de Biol., Sept. 10, 1903), to determine its toxicity in various animals under different conditions. Injected intravenously in rabbits, it was markedly toxic, but was less so when injected under their skin, in which case it produced an extensive gelatinous edema at the point of injection. The temperature of 55° C. destroyed the toxicity of the serum at the end of three hours, and markedly reduced it at the end of fifteen minutes. An exposure to the air for fifteen days destroys the toxic power. This is also equally diminished in contact with ether or chloroform. The toxicity is not affected by filtration through a Berkefeld filter. The serum of the deer has a marked destructive effect in the red blood cells of various animals. This serum after having lost its toxicity by heating to 55° C., does not regain it by the addition of other fresh serum; consequently, the toxic constituents present in its natural state correspond to certain bacterial toxins rather than to the hemolysines. By means of small doses of the fresh serum, or even by means of the serum rendered innocuous by heating, it is possible to strongly increase the resistance of rabbits to the strongest doses of the serum. The serum of these animals, thus fortified, will protect other normal rabbits against the serum of the deer, whether the former be injected directly into the veins, or be mixed in the test-tube with the deer's serum about to be administered. Rabbits which have been made capable of supporting large doses of the deer's serum, are also capable of withstanding a dose of the serum of the ox greatly in excess of the dose fatal in a control animal. This fact lends support to the view that the toxic substances met with in the blood of various mammals, if not identical, are at least closely related.

Experimental Tuberculosis.—Goats, oxen and horses are found by J. De Haan (Virchow's Archiv, Vol. 174, No. 1) capable of being rendered tuberculous by means of pure cultures of tubercle bacilli obtained from sputum, provided the animals are in poor condition. Macroscopically and microscopically the lesions are identical with those of tuberculous animals of Europe. There seems to be no racial immunity, and the infrequency of tuberculosis is to be ascribed to favorable environment. The monkey was found to be very susceptible. In all infected animals the lungs and bronchial lymph-nodes were involved, with or without tuberculosis of the mesenteric lymph-nodes. The intestines were generally intact.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, DECEMBER 12, 1903.

SANITARY DEVELOPMENT OF STREET CLEANING.

In the paper read before the New York Academy of Medicine on Thursday, December 3, 1903, Dr. Woodbury, the Commissioner of the Street-Cleaning Department of the municipal government of Greater New York showed very forcibly how much a physician can accomplish in the work of organizing and directing this important branch of city government. The improvements that have been introduced in the department's methods as the result of his term of office will undoubtedly prove the basis for a street-cleaning department in New York that will eventually prove a model for the world. There is no doubt that Dr. Woodbury has exhibited thoroughly progressive views in the matter, and has begun, as far as his short term of office would allow, the introduction of improvements that make street cleaning not a haphazard expenditure of the appropriation allowed for the purpose, but a definite organization of the disposal of city waste in such a way as to secure the best results with the least expenditure to the municipality.

It has long been known that the waste material of a great city was extremely valuable and that under proper conditions the collection and disposal of it might very well be made not only to pay for itself but actually to leave a surplus of revenue. So far there has been apparently very little thought of possible applications of this principle in the disposal of the extremely valuable waste of New York City. Now there has been a beginning of it. The ashes are being used for filling in near one of the islands in the harbor and already nearly one hundred acres of valuable land have been reclaimed from the water. This of itself constitutes an excellent financial showing. After small beginnings, in scarcely more than an experiment station, at least one good plant for the disposal of city rubbish has been constructed. In this it has been found that enough fuel is constantly being burned to supply an immense amount of valuable energy. This energy is now being used for lighting for another plant of the street-cleaning department, and may very well be further employed for city lighting purposes. Even the garbage is not entirely a source of expense, and street cleanings are being disposed of as manure, for which of course the material is very suitable.

A valuable element of Dr. Woodbury's work, however, is that especially which he has been able to accomplish because of his training as a physician. From the very beginning of his term he came to the realization that the open street markets for food materials in the crowded portions of the city on the lower East Side were a constant source of danger to the health of the city. Besides being a public nuisance because of the obstruction of the streets, they are a hindrance to the street-cleaning department's work for the reason of the crowds that constantly gather near them, and the source of very offensive littering of a quarter of the city already below standard in the matter of health. Underneath the new Williamsburg Bridge places were found for the fish market and other food product markets that formerly occupied places along the curbs in such crowded streets as Hester and Rivington. This change will undoubtedly be reflected in the mortality and morbidity records of the city in a very short time.

An important part of Dr. Woodbury's paper was taken up with the discussion of the number of microbes that occur in various portions of the city, and a stereoscopic demonstration of the bacteriology of the various districts which makes very clear the reason why the mortality should be so much higher on the lower East Side than it is on upper Fifth Avenue. Agar culture plates exposed for fifteen minutes in Hester Street give thousands of colonies of bacteria, while in the better residential quarter of the city the same ex-

posures result in, at most, a few scattered colonies, most of non-pathogenic and a few even more harmless molds. The necessity for thoroughly cleansing these crowded portions of the city and for making the index of the success of the street-cleaning department not quite so much the satisfaction of the dwellers on Fifth and Madison avenues, but the health statistics of crowded quarters, is very evident.

Dr. Woodbury has shown this new lesson in a very striking way. We congratulate him on the work that has been accomplished. We are elated to find that a physician should have shown such favorable possibilities for the practical organization and development of a great city department. The new city government now has a model before it that it cannot ignore without expense to popularity and the further evolution of the street-cleaning department into an, at least partially, self-supporting municipal bureau must be the criterion of the fitness of Dr. Woodbury's successor.

The demonstration of his fitness in a managerial capacity should prove the advisability of putting a physician in charge of the New York City Board of Health. There has been an impression that the laws of New York State forbade the appointment of a physician as the head of the department of health of this city. Even the President of the New York State Medical Association stated in his address at the recent annual meeting that a physician might be elected President of France but not of the New York City Board of Health. This was true under the old city charter but under the new charter, as stated by the counsel of the New York State Medical Association, in the December number of the journal of the Association, it is no longer true. We are in a time of specialism; and sanitary experts, known to be such, should be chosen as the heads of both the departments of health and of street cleaning.

AN OLD FRIEND IN NEW ROLES.

Ergot has long been one of the standard drugs, with whose use every medical practitioner was familiar at least in his obstetrical work. In recent years, however, the efficacy of the drug has been proven in a number of conditions and it would seem that it may be considered by the next generation of physicians as one of the most important substances in our therapeutic armamentarium.

At the recent meeting of the New York State Medical Association the employment of ergot was once more discussed in regard to its effect in alcoholism and in drug addictions of various kinds. A number of conservative observers have used ergot by hypodermic injection especially in alcoholic cases and have found it to give very satisfactory results. Surgeons especially did not hesitate to say that in surgical cases complicated by alcoholism no drug was equal to ergot in quieting the patient, preventing delirious complications, and restoring the individual to a restful condition.

The report of the experiences at Bellevue Hospital in New York seems to prove that ergot is of benefit even in the most advanced alcoholic conditions and under circumstances in which ordinarily there would appear to be very little hope of a favorable issue in the case. Dr. Alexander Lambert has found that in the so-called wet brain of alcoholics, an almost inevitably fatal condition, ergot given hypodermically proves life saving in a great many cases. Where formerly he was satisfied to save two or three out of thirty or forty patients, using all of the ordinarily recommended remedies, he now has but two or three deaths from this condition during his term of service.

This is, however, not the only purely medical field in which ergot has attracted attention in recent years. In cases of chronic malarial poisoning ergot has been found more satisfactory than even quinine for the prevention of the more serious symptoms. It has been found that when surgical operations are performed upon those who have previously suffered from severe malaria it is not unusual to have symptoms of malarial fever occur a few days after the operation. The disturbance of circulation incident to the operation seems to allow the escape of malarial parasites from the spleen where they had been stored. In these patients it has been found that the use of ergot for some time before an operation and shortly after it, inhibits and often prevents the development of malarial symptoms. In other cases of chronic malaria an end can be put to the recurrence of so-called attacks of dumb ague by means of ergot.

In chronic diarrhea ergot has also been found a very useful drug. Its special field appears to be the serous or seromucous diarrheas of adults in which nervous conditions are the most important etiological factors. The vasomotor paresis which develops in these cases and permits the free outflow of serum from the dilated blood vessels of the intestinal wall is prevented by the toning up of these blood vessels consequent upon the effect of ergot. In bacterial diarrheas, especially at the beginning, the outflow of serum is of itself a protective effort on nature's part to assist in the throwing off of the offending micro-organisms

and this protective mechanism must not be interfered with. After a time the diarrhea seems to continue as the result of the formation of a bad habit of relaxation on the part of the intestinal vessels and then ergot has a distinct field of usefulness.

It is not unlikely that in the serous conditions incident to other diseases ergot may prove to be a most important agent. Edema of the lungs still continues to be an extremely fatal disease in spite of all therapeutic efforts. Since ergot has proved so beneficial for edema of the brain, its use here would seem to be especially indicated and, as a matter of fact, some cases have been reported in which recovery has taken place in what would otherwise have proved to be fatal pulmonary edema. In dysentery, at times, the outflow of serum from the blood vessels proves a culture medium for the rapid multiplication of the micro-organisms present in the intestine. Under these circumstances the use of ergot would seem to be indicated.

In all these cases the drug should be used up to its full physiological effect. With regard to alcoholism especially subcutaneous injections of half a dram of a fluid extract of ergot containing 12½ per cent. of the drug should be employed. This should be repeated as often as is necessary, or until there is a definite improvement in the patient's condition. As was very well said by several of the participants in the discussion at the New York State Medical Association meeting (see Medical News, October 31, p. 852) to have due success in the use of ergot the ordinary ideas with regard to the dosage of the drug must be revolutionized. To give small amounts is to invite failure, while so far the use of larger doses have produced no serious effects and it would seem that none need be feared. Further investigation of the uses of ergot in these and allied conditions may make the drug one of the most useful in the Pharmacopœia.

DO LIVER AND KIDNEY CELLS REGENERATE?

It is beyond our ability to foretell at what point that branch of surgery will end which depends for its success upon the belief that variously diseased parenchymatous cells will regenerate in the presence of an increased and altered blood supply.

In the last seven years the operation of epiplorrhaphy has been performed several hundred times, due to the stimulus given it by the success in 1895 of Rutherford Morison. Greenough, of Boston, has recently collected particulars of 105 patients with cirrhosis of the liver with ascites due either to alcohol, syphilis or malaria, that had been operated on by the Talma technic. It will be remembered that this is based upon the belief that the ascites is due to mechanical obstruction rather than to an effort on the part of nature to cast off certain poisonous substances from the blood which the damaged liver cells can no longer break down into the elementary excretory products of metabolism.

Of Greenough's 105 patients, 31 died within thirty days of the operation, 29 recovered and lived upward of thirty days without showing any improvement. Forty-four showed some improvement, but in many of these the time elapsed after operation was very short. Sixteen had died at periods ranging from one to twenty-four months after operation and only nine were alive and free from ascites more than two years after the radical treatment had been instituted.

Brewer's statistics, given in his recent textbook, are somewhat more favorable. He records a mortality of 37 per cent. with 20 per cent. of marked improvement and 10 per cent. of cures. In the opinion of this author these results seem to warrant its continued trial inasmuch as the mortality a few months after ascites has developed is about 100 per cent. Those who favor the operation describe the high mortality in part to the belief that ascites may in many cases be looked upon as a sign of approaching death.

Sinclair White, in the *British Medical Journal*. Oct. 10, 1903, says that the testimony of competent observers, who during operation "have been able to satisfy themselves by sight and by touch that well-marked cirrhosis was present in patients who subsequently recovered and remained free from recurrence of the ascites, is not easily set aside."

Talma and Drummond claimed for the operation merely that it would cure or relieve ascites by providing abundant anastomosis between the portal and systemic veins, but there seems to be reason for believing that it may accomplish more than this. As, with the improvement in technic, there is a decrease in mortality and less fear of the operation, it becomes possible for the surgeon to obtain cases before the patient's state is hopeless, there may be possible an actual regeneration of the old or even a creation of new parenchymatous cells. This idea has been exploited in the recently developed operation of decorticating the kidney for chronic nephritis.

While clinicians are striving to determine the validity of the claims in favor of this technic, re-

search students are attacking the problem from the laboratory standpoint. Haven Emerson, in a paper read before the Association of the American Physicians, Washington, 1903, as a result of a series of experiments at the Columbia laboratory, concludes that "in the dog, where the decapsulation is intraperitoneal, we have marked vascular connection with important viscera, not with fatty tissue, and so marked a formation of connecting tissue penetrating the parenchyma from the new capsule as to present the picture of a beginning interstitial nephritis. Where we find vascular connection we see the most serious lesions of the renal parenchyma. Where the real lesions are not found, we see no formation of new blood vessels."

It is unusual to find accurate laboratory and clinical evidence at variance for any length of time, but at the present moment there is a wide diversity between the opinions just quoted and those of Edebohls and his followers, who have been practising decortication very widely. It may be possible that these dissenting views will have a clearer relation to each other if it becomes possible for the subjects of the clinical and laboratory workers to be similar. In the one case the patient was a healthy dog, in the other a diseased human being.

Leaving the ultimate question of cell-regeneration for future decision, and considering only the expediency of what may be termed sanguiducent operations for the relief of symptoms which destroy life, there appears to be ground for the statement that in chosen cases they should be undertaken. As yet they are restricted to the relief of the liver and the kidney. There is before the medical world to-day no question more profoundly important nor fraught with greater possibilities than the determination of the efficacy of a technic which enables one at will to modify and to deflect the circulation of the abdominal viscera.

HOPE IN THE HOME.

The second lecture under the auspices of the Phipps Institute was delivered by Dr. William Osler, in Philadelphia. The subject, "The Home in Its Relation to the Tuberculosis Problem," was as striking in its forceful presentation of the Home Treatment of Disease, as Dr. Trudeau's paper, published six weeks ago, was of his personal experience with Sanitarium treatment.

The historical handling of the treatment of tuberculosis, though presented merely in the form of allusion, is convincing; for Dr. Osler has focussed the individual rays of past experience upon the work of the present decade, even of the present year, and has shown that there is no insurmountable difficulty in carrying into the homes, where 98 per cent. of tuberculous patients must be treated, the educational propaganda that will sooner or later lessen the sources of infection.

The possibilities that he outlines, of efficient Board of Health inspection, of philanthropic scientific house to house instruction, and of home treatment by fresh air and proper food is intensely practical as well as very suggestive. When Dr. Osler sums up other men's experiences he does it with a critical sense born of his own knowledge that enhances the value of his data. And such an article should justly lead many a physician to confidently assume the home treatment of patients who could not go away; and whom they otherwise would give up.

ECHOES AND NEWS.

NEW YORK.

Mosquito Extermination.—On December 16, at 2:30 P.M., in the rooms of the Board of Trade and Transportation (Mail and Express Building, Broadway and Fulton street), will be held the first general convention on the subject of Mosquito Extermination, and all that implies in the way of health, drainage for agriculture and other objects, scenic improvement of foul, wet places, etc., etc. Speakers of national reputation from all sections are on the program and the themes comprise a review of the progress of the movement for extermination from a number of different viewpoints.

Omission in Report of Genito-Urinary Section of Academy.—In our last week's report of this Society we omitted to credit Dr. John Van der Poel as the author of the cases of "Retention of the Urine Due to Foreign Body in Bladder of Uncertain Origin," and of "Extravasation of Urine Due to Phimosis."

State Health Matters.—According to the bulletin of the State Board of Health for October, there were no deaths in three towns in the State during that month. These healthful communities were Malone, with a population of 5,935; Camden, with a population of 3,745; and Westfield, with a population of 2,430. Baldwinsville, with a population of 3,000, and Walton, population 4,869, each reported one death in the month. The total number of deaths in the State for the month was 9,786, or 226 more than the average for the last five years.

Professor Allchin Clinic at Roosevelt Hospital.—Professor Allchin of the Westminster Hospital, London, gave a very interesting talk before the students of the College of Physicians and Surgeons, at the Syms operating theater, Roosevelt Hospital, on Dec. 7. He was introduced by Professor Walter B. James, and devoted a part of the hour to an exhibition and explanation of a case of acute articular rheumatism. He said in part: "There are fewer cases of acute articular rheumatism now than formerly, and the chief symptom, pain, lasts for a much shorter time. This is due largely to the use of salicylates as a specific. The two principal symptoms are pain and

affections of the heart. The former accompanies the disease in children, but is much less severe than in adults, and lasts only a few hours. It is common to see a child suffering severely in the morning, and find that it is able to run about and play in the afternoon. In this class of cases the salicylates seem to be of much less value than in adults. The heart lesions in children are dominant; but loudness of a murmur is not characteristic of the state or severity of the lesions producing it. As complicating factors you may expect, and are very likely to find, chorea, endocarditis, pericarditis, subcutaneous nodules, sore throat, and acute tonsillitis. In the adult the dominant symptom is pain coming on suddenly, and persisting for one or two weeks under treatment. The heart is not seriously involved, and usually escapes if there was no previous disease."

Prof. Allchin spoke very cordially of American physicians and was thankful for the honor bestowed upon him in being allowed to address in a didactic fashion the body of students before him. Professor James announced that Prof. Allchin's System of Medicine will be placed in the medical library of the college as soon as the recommendation is ratified by the Committee on Accessions.

Fee for Deficients' Examinations at College of Physicians and Surgeons.—According to a recently published rule of the Faculty at Columbia all students in the medical department of that university who are found deficient upon examination will be required to pay a fee of $5. This applies especially to conditions attendant upon the regular spring test of each year, and every student who is obliged to come up in September must pay the fee for his particular series, it being understood that no one can advance with his class who carries more than three deficiencies. Failure to pass at the first conditional examination entails a charge of $5 for a second trial in each subject in which the student is still deficient, and he may not advance with his class until such deficiency is made good. It will be interesting to note whether this rather severe provision will increase the college exchequer or elevate the standard of scholarship. If the latter result is brought about there will be no question as the efficacy and wisdom of the plan as above outlined.

Presbyterian Hospital Report.—The annual report of the Presbyterian Hospital has just been issued, and shows that a greater number of medical and surgical cases have been received than ever before in its history. The present accommodations of the hospital are taxed to their utmost, and the demands for care and treatment are yearly increasing. Although the annual deficit continues to be large and this year amounted to $58,504.88, the work of the hospital has not been curtailed, as the managers have had faith that the public will sooner or later appreciate the charitable service rendered, the absolute necessity of it, its importance to the public health, and also the great value of the educational work in the training of physicians and nurses. During the fiscal year ending September 30, 1903, 71,235 days of treatment were given to 3,214 patients in the hospital wards and private rooms, the average being 195 per day, which is as many as the present capacity of the hospital will admit of without unwise overcrowding. The average time spent by each patient in the hospital was twenty-two days. Of these patients 68 per cent. were unable to pay anything and were treated free, 6 per cent. were on endowed beds at the request of those having the right to nominate patients for such beds, and were therefore not charged for treatment, 17 per cent. paid only $1 per day, and the remainder, 9 per cent., were private-room patients and were charged little more than the cost of their care. The average cost to the hospital, including all special nursing furnished, has been for ward patients $2.51 per day. The dispensary has the services of 46 physicians, of whom 23 are on duty each week day from 1:30 to about 5 P.M. Prescriptions given are filled at the pharmacy for the trifling fee of ten cents, regardless of the real cost of the medicine, and without charge if the patient is unable to pay. The same patient may come daily as long as his or her condition needs the attention of the physician. During the past year, 30,092 persons made 81,219 visits, being an average of 269 per day and an average of 3 visits by each person; 82,488 prescriptions and 20,698 surgical dressings were furnished. The average amount paid by patients per visit was 12¼ cents, and the average cost to the hospital per visit, including prescriptions and dressings furnished, was 11¾ cents. During the past year the ambulance responded to 2,844 calls, an average of 8 per day. Of this number 394 patients were treated by the ambulance surgeon, and then taken to their homes or left at place of call, not needing further hospital treatment. The cost of the ambulance department was about $3,946 during the year, and the revenue to the hospital $16. While there are several other hospitals in the vicinity, this is the only one maintaining an ambulance service ready day and night for immediate calls. The pathological department is an important and indispensable factor in the examination of practically every patient admitted to the hospital. More than 18,000 bacteriological, histological, microscopic, and chemical studies and analyses have been made during the year.

Tenement House Commission Report.—Robert W. de Forest, the Tenement House Commissioner of New York City, has transmitted to Mayor Low the first report of New York's new Tenement House Department. In it he says: "On January 1, 1902, a new department of the city government known as the Tenement House Department was created. Since that time all the tenement houses in New York have been examined and their condition ascertained. Tenement conditions in many instances have been found to be so bad as to be indescribable in print; vile privies and privy sinks; foul cellars full of rubbish, in many cases of garbage and decomposing fecal matter; dilapidated and dangerous stairs; plumbing pipes containing large holes emitting sewer gas throughout the houses; rooms so dark that one cannot see the people in them; cellars occupied as sleeping places; dangerous bakeries without proper protection in case of fire; pigs, goats, horses and other animals kept in cellars; dangerous old fire-traps without fire escapes; disease-breeding rags and junk stored in tenement houses; halls kept dark at night, endangering the lives and safety of the occupants; buildings without adequate water supply—the list might be added to almost indefinitely. The cleansing of the Augean stables was a small task compared to the cleansing of New York's 82,000 tenement houses occupied by nearly three millions of people representing every nationality and every degree in the social scale. The task that confronted the Department was not, however, limited to this. Without organization, without employees, with all its problems before it, it was on the very day that it came into existence confronted with an organized and vigorous attack in the legislature upon the fundamental principles of the law for whose enforcement it was created. Without previous records, with almost no information in re-

gard to the condition of the existing tenement houses, it was called upon to carry out an important and far-reaching scheme for their improvement, involving the structural alteration of over 40,000 buildings. In the period under consideration in this report a new branch of the city government has been organized, its machinery created and a force of about 400 employees trained, disciplined and educated; far-reaching and important advances in legislation have been secured as a result of the Department's action, and radical and vicious attempts to break down the tenement laws defeated. Living accommodations for 16,768 families, or 83,840 persons, have been provided in sanitary, comfortable and decent houses, each one of which has been built according to law; notorious evasion of and non-compliance with the laws has given place to their complete, uniform and impartial enforcement; the evil of prostitution has been practically abolished in the tenement houses; 337,246 inspections have been made; 55,055 violations filed; 21,584 repairs made to plumbing; 13,617 water-closets cleaned; 11,611 accumulations of filth removed from cellars and other parts of such buildings; 13,732 ceilings cleaned; 15,364 walls cleaned; 10,060 unsafe wooden floors removed from iron fires-escapes and new iron floors substituted; 1,701 fire escapes erected on buildings that before were without this protection. The registration of 44,500 owners' names has been secured, thus fixing the responsibility for bad conditions in the tenements; contagious disease has been checked and prevented; 32,825 citizens' complaints have been investigated and the conditions complained of remedied; and an important tabulation and presentation of the population in every tenement house block in the Borough of Manhattan has been prepared that will be of incalculable value to the city. The existing tenement houses have been frequently and systematically inspected; foul cellars have had the accumulated filth of years removed; defective and unsanitary plumbing which has apparently existed for long periods has been remedied; houses unfit for human habitation vacated; hundreds of houses have been radically reconstructed and improved; light has been let into dark rooms; vile yard privies and privy sinks have been removed, and the whole sanitary condition of the city raised to a higher standard. The results of this work are clearly reflected in the reduced death-rate, which in 1902 was 18.7 as compared with 20.0 in 1901, and in the first eight months of 1903 has been reduced to 18.0. To those who have borne the burden of the organization of the new department what has been done seems but a beginning—a first step in the endless fight against disease and death." The report is the most comprehensive report on this subject that has ever been made by a city department and will shortly be printed, in two volumes of about 1,000 pages. It will contain many photographs, plans, and other illustrations. One of the leading features of the report is a series of colored maps, showing population, density of population and the nationality and the number of families living in each block throughout the tenement districts of the Borough of Manhattan. The report includes, among other subjects, the following: Houses Unfit for Habitation, Citizens' Complaints, Periodic Inspections, Contagious Disease Inspections, Neglected Houses, Disease Houses, Condemnation of Rear Tenements, Municipal Tenements, Janitors, the Structural Improvement of the Old Houses, Privy Sinks, Dark Rooms, Fire Escapes, Prostitution, The New Law Tenement, Dampproofing, The Enforcement of the Law in New Buildings, Legislation, Opposition to the Department and Law, The Relation of the Department to the Public, The Registration of Owners' Names, Co-operation with Other Departments, Employees, Corruption Checked, Inspector's Equipment, Women Inspectors, Departmental Instructions, Organization of the Department, Plumbing, Cellar Rooms, Bakeries, Rentals and Vacancies.

PHILADELPHIA.

Dr. Van Lennep Honored.—The fiftieth birthday of Dr. W. B. Van Lennep, Professor of Surgery at the Hahnemann Medical College was celebrated December 5 by a banquet tendered him at the Hotel Bellevue by a number of physicians and surgeons of the city. Several toasts were responded to, and Dr. Van Lennep was presented with a silver punch bowl.

New Hospital at Uniontown.—The Uniontown Hospital, erected at a cost of $100,000, was recently opened for the reception of patients, five of whom were received the first day. The hospital, which is one of the best equipped in the State, will accommodate about 100 ward and 14 private patients. The staff includes 15 physicians.

The Typhoid Epidemic at Butler.—The typhoid epidemic at Butler, Pa., is now believed to be practically under control. The new cases are decreasing and the work of caring for the patients has been systematized by Dr. M. S. French, of Philadelphia, who is practically in charge. The twenty-five nurses sent from Philadelphia are looking after the patients in the Hospital of the City of Brotherly Love, which was organized in a vacant hotel. The hospital is in charge of Dr. L. H. McKinnie, lately a resident at Jefferson Hospital. Dr. F. C. Johnson, who was sent by Mayor Weaver to investigate the condition at Butler, has returned to this city and furnished an exhaustive report of the situation. He states that the epidemic was caused by the pollution of the sources of water supply, the serving of the city with unfiltered water thus polluted, and neglect on the part of the citizens, even after being warned to sterilize by cooking all articles of food and to boil all drinking water. The report states that the tragic feature of the epidemic is the fact that it was absolutely preventable and that with plenipotentiary powers in the hands of the Health Bureau it might have been prevented.

Observations on Aneurism and Arteriosclerosis.—The Mütter lecture on Surgical Pathology for 1903 was delivered before the College of Physicians of Philadelphia on December 1 by Dr. C. N. B. Camac, of Cornell University, who spoke on the above subject. Dr. Camac dwelt at some length upon the historical aspect of aneurism and the numerous theories regarding its causation. He then detailed the results of a long series of experiments made with the object of determining the nature of the change in the elastic tissue of the media which is probably the first change in the development of aneurism. He studied arteries from 33 persons, staining them all for the elastica. The arteries included both normal and abnormal conditions. Müller-formol was found to be the best fixing agent, and Weigert's stain gave the most satisfactory results. The elastic fibers in the diseased vessels were found to be straighter than normal in some instances and fewer in number, but they showed no change in histological structure. Dr. Camac next experimented with chemicals to determine if changes could be detected in this manner. Acetic acid and potassium hydrate were used as digestants, but the

latter was found not to be feasible. Acetic acid in from 5- to 15-per-cent. solutions was found to be available, but a long series of tests showed that no histological change could be demonstrated. The change in the elastica preceding aneurism is believed then to be a physical or molecular change. Regarding the relation of general arteriosclerosis to aneurism, Dr. Camac stated that it is not a necessary feature of the latter. Broadly speaking, the presence of arteriosclerosis suggests the probability that aneurism will not occur. Dr. Camac showed many microscopic specimens of the tissues studied. Before the lecture Dr. Camac was entertained at a reception given by Dr. George McClellan.

The Smallpox Situation.—Smallpox continues to increase, more than half of the wards of the city containing one or more cases of the disease. During the week ending December 4 there were reported 99 new cases, an increase of 29 over the preceding week. Since the beginning of the year, 1,579 more cases have appeared than were known during a similar period two years ago. Negroes are the greatest sufferers, as they, more than whites, refuse to be vaccinated. The following instructions to vaccine physicians have been issued by Director Martin: (1) Every vaccination shall be preceded by a preliminary cleansing, accomplished by means of green soap, alcohol and water; (2) the abrasion shall be made by means of a scarifier or lancet, which must be sterilized before and after each vaccination by flaming with alcohol; (3) the abrasion must not cause more than punctiform hemorrhage. When properly performed there should be no blood; (4) virus must be thoroughly incorporated with blade of lancet or with sterile glass rod; (5) when sufficient time cannot be given for arm to dry a piece of clean wax paper should be applied to abrasion and secured by strip of zinc oxide adhesive plaster; (6) all cases of vaccination shall be seen in the second week, and the date of the second visit must be incorporated in the report, together with statement as to whether vaccination was successful or unsuccessful, a failure to make report of the second visit relieving the city from all pecuniary obligation; (7) unsuccessful vaccinations must be repeated.

Obstetrical Society.—At the meeting of the Philadelphia Obstetrical Society, December 3, Dr. William R. Pryor, of the New York Polyclinic Medical School, by invitation addressed the Society on the subject of "Puerperal Sepsis." Following the address Dr. Pryor was entertained at a reception given by the President of the Society, Dr. J. M. Fisher.

CHICAGO.

Appointment of Dr. Biehn.—Dr. Joseph F. Biehn was certified to by the Civil Service Commission as city bacteriologist and superintendent of the milk and food inspection bureau, after passing a competitive examination. He was graduated from the Northwestern University Medical School in 1901, and has been instructor in bacteriology since that time. His salary will be $2,000. His duties as professor of bacteriology at Dearborn Medical College will not interfere with his work in the city laboratory.

Pathologist at Manila.—Dr. Maximilian Herzog, who for more than seven years has been Professor of Pathology and Bacteriology in the Chicago Polyclinic, has been appointed pathologist in the Bureau of Government Laboratories at Manila.

New Hospital.—The Hospital Daughters of St. Joseph are going to start work as soon as plans are made on a four-story fireproof hospital, to be erected on the east side of Harvard avenue, between Sixty-third and Sixty-fourth streets. It will be 180 x 80 feet, pressed brick and stone front, and will contain about 80 rooms, and 5 wards. The cost will be $80,000.

A New Institution.—A new institution will be built soon at North Forty-third avenue and Church street for the St. Joseph's Orphan Asylum. The various buildings will include a three-story fire-proof hospital, 60 x 170 feet in ground dimensions; two-story chapel, 62 x 32 feet, and one-story power and laundry plant, 42 x 40 feet. The total cost is estimated at $80,000.

Bone Changes in the Fetus.—In a paper on this subject, Dr. Frank S. Churchill said there were striking departures from the normal in the appearance and structure of bone, both macroscopically and microscopically. These changes are found widely distributed, but most frequently in the long bones, and especially in the epiphysis. The processes of cartilage production and bone production go on in rachitic bone, but in disturbed relations, cartilage production being excessive and ossification deficient. The result is a bone deficient in lime salts, thickened and flexible, and upon these characteristics depend the deformities seen in rickets. Over-cartilaginous production causes thickness; hence the bosses seen on the skull, the rachitic rosary, the broadening of wrists and ankles. Deficient ossification makes the bone softer, and more easily bent when exposed to the pressure of bodily weight and muscular action; hence the deformities of the spinal column and pelvis, the curvature of forearm, thigh and leg, the greenstick fractures. As the long bones increase in length by ossification at the junction of the epiphysis and diaphysis, shortening of the limbs is also seen, due to a failure of this process, producing a dwarfed effect. On section of a rachitic long bone, the principal change is seen at the ends, where the cartilage layer uniting shaft and epiphysis is seen to be much thickened and broadened, with irregular and ill-defined edges, unlike the narrow, well-defined line of the normal bone. This cartilage area is of a bluish color, is softer than normal, and the calcified spots are irregular and scattered. In the shaft, the outer layers of the bone are thickened and soft; the inner layers more thoroughly ossified, the medullary canal more vascular and resembling granulation tissue. Microscopically, the cartilage cells in the zone of proliferation are found to be piled up on each other, not arranged in regular columns. The line between cartilage and advancing bone is irregular, and not well defined. Eyelets of bone are seen in epiphyseal cartilage, and parts which should be completely ossified are still cartilaginous. There is also a great increase in the number and size of the blood-vessels. In the shaft are seen more or less thickening and increased vascularity of the periosteum. Instead of hard compact bone is seen irregular spongy masses. After a variable length of time, say from three to eighteen months, the active proliferation in the cartilage and periosteum ceases, and is gradually replaced by ossification. Condensation and retraction often occur in the spongy masses of bone, and the ultimate result is sometimes an ivory-like structure harder than normal bone, a condition noticed by surgeons operating upon patients who have suffered from rickets in early life. He described the less frequent changes that are found in the spinal column. He also mentioned the changes which may take place in the pelvic bone. The development of rachitis is preventable except among the extremely poor. Given a normal new-born infant, with a fairly intelligent mother, the physician can correct the first stage of

malnutrition, and by intelligent methods of feeding insure proper growth and development. But he must be keenly watchful for the first disturbance of nutrition, and then take vigorous action along dietary lines.

GENERAL.

Addition to Orange Hospital.—Plans are being considered to make a large and important addition to the Orange Memorial Hospital. The institution has been overcrowded for a long time, and it is planned to erect an extensive addition costing from $60,000 to $75,000. Work will probably be started early in the spring.

Psychopathic Ward in University of Michigan.—The psychopathic ward at the hospitals of the University of Michigan is now nearly ready for occupancy. The State made an appropriation for the cost, but the University added $5,000 from its own funds to fire-proof the upper part of the building. The University authorities felt that they could not be free from blame if any of the peculiar class of patients for which the psychopathic ward is constructed should be injured through lack of the greatest precautions against fire.

Arsenic in Food Ruled Against by London Commission.—The royal commission on arsenical poisoning from food and drink has recommended the prohibition of the sale of beer and other liquid food, or of any liquid entering into the composition of food, which contains one-hundredth of a grain or more of arsenic per gallon, and the prohibition of the sale of solid food containing one-hundredth of a grain per pound. The commissioners find there are serious defects in the present machinery available to safeguard the public.

British Food Statistics.—According to Major P. G. Craigie of the Royal Statistical Society, the annual food imports of Great Britain during the years 1889-91 amounted to $23.20 per head of population. Nearly half of Sir Robert Griffin's estimate of £11 per head as the average outlay for all forms of food and drink of the Briton is spent on imported foods. The use of meat had greatly increased. In the 1857-59 period sea-borne meat amounted to but five pounds per head; now it is over fifty-three pounds. He suggested that possibly this large increase in the use of meat had not been wholly beneficial in its effects on the health and prosperity of the nation.

Medical College Burned.—The medical college building at the University of Vermont was burned to the ground Dec. 2, 1903. The loss of $20,000 is covered by insurance. The building was presented to the university in 1884 by John B. Howard.

Physician's Certificate before Marriage License.—The Iowa Society for Suppression of Disease and Degeneracy has prepared a bill to be introduced in the coming general assembly providing for a physician's certificate of examination before a marriage license can be issued.

Medical Press Exhibit at the St. Louis World's Fair.—It is to be regretted, as a matter of history and of criticism, that no International Exposition has ever had an exhibit of the medical and scientific publications of America, as a collective and comprehensive exhibit. A few scattered displays made by individual publishers, or included in the general newspaper exhibits, were all that served to represent the American Medical Press either at Chicago or at Paris. It is true that at Buffalo a commendable effort was put forth by the department of press and publicity to keep on file the current issues of all American publications. This plan was only partially successful. Mr. Walter Williams, through the Missouri Board of Commissioners, is preparing an exhibit of journalism, but this will embrace only the publications of Missouri. The undersigned has secured adequate space at St. Louis, in the palace of Liberal Arts, with a view to making a display of American Medical publications which shall be commensurate with the importance of this class of work, and earnestly solicits the cooperation of editors and publishers of medical journals. Decisive action must be taken at once. The expense necessary to make this exhibit will be nominal. There is no charge for space, and the writer believes that the department of publicity will assist us in maintaining an up-to-date and comprehensive exhibit, where files of current issues of every medical journal in the land may be found during the progress of the great fair. Full information will be furnished later, and all medical journalists are urged to communicate at once with the undersigned with a view to united action and early endeavor so that additional space may be secured if necessary to accommodate all who desire to join the bureau. Chas. Wood Fassett.

Wheeling Medical Library Association.—The annual meeting of this association was held December 5. The proceedings consisted of reports of the Secretary and Librarian, Dr. W. H. McLain; President's Address, Dr. F. L. Hupp; Symposium Phototherapy. Short papers by Dr. J. S. McClellan, Dr. G. Ackerman, Dr. J. Schwinn. Discussions were opened by Drs. Wingerter and Noome. This is the sixth year of association, with a library which now contains 4,000 books and 25 journals on file.

Obituary.—Dr. R. D. Murray, a yellow fever expert of wide reputation, and dean of the Marine Hospital Service, died in Laredo, Tex., yesterday, from injuries sustained in a runaway accident a week ago. He was a native of Ohio, sixty-four years old, and was a Civil War veteran. For several years he held the chair of instructor of anatomy in a Cleveland medical college. He entered the Marine Hospital Service in 1872, and was in charge at Norfolk, Va.; Mobile, Ala., Philadelphia, New Orleans, and Key West, Fla. The interment will be in Bluffton, Ohio.

Dr. Horace M. Paine, who died last Sunday morning in Atlanta, Ga., was one of the best known homeopathic physicians in New York State. He was born in Paris, Oneida county, on Nov. 19, 1827. He was graduated from the University of the City of New York in 1849. He practised his profession in Clinton and Albany, in the latter city thirty-one years, and relinquished active work in 1895, since which time he had lived in West Newton, Mass., and in Georgia with his sons. He was one of the founders of the Homeopathic Medical Society of the State in 1850 and served it later as secretary and president. He was prominent in the long effort by which his school became legally recognized in New York. For twenty-one years he served as one of the State homeopathic examiners, was one of the first trustees of the Albany Homeopathic Hospital, an incorporator of the Middletown State Hospital and was largely instrumental in securing the legislation establishing the Gowanda State Hospital. He was a member of the American Institute of Homeopathy, the Hahnemann Association, of several similar local societies and an honorary member of many homeopathic societies here and abroad. He leaves a wife, to whom he was wedded fifty-one years ago; three sons, Dr. Howard S. Paine of Glens Falls, Dr. N. Emmons Paine of West Newton, Mass., and Dr. Clarence M. Paine of Atlanta, Ga., and one daughter, Miss Emily F. Paine of New York. Dr. John M. Paine, curator of the Metropolitan Museum of Art, is an only brother.

Dr. William H. Holmes died last Monday night in his home at 48 Hillyer street, Orange, N. J. He was

born in New York sixty-nine years ago. Dr. Holmes had lived in Orange for the past thirty-nine years. He had suffered from heart trouble and Bright's disease for a year and these contributed to cause his death. He served in the navy as an Assistant Surgeon during the Civil War, holding the rank of Lieutenant. He is survived by his wife, who lives in Jersey City.

Dr. Joseph M. Harcourt, who came from Ireland in the early '50s, died last Monday at his home, 110 Decatur street, Brooklyn, in his eightieth year. He was a member of the Kings County Medical Society. He was known as a linguist, a mathematician and writer on professional subjects.

CORRESPONDENCE.

RE "SPECTACULAR PROPHETS."

To the Editor of the MEDICAL NEWS:

DEAR SIR: Referring to the criticisms of your editorial on page 945, issue of November 14, 1903, there is one slight error, into which you have fallen, and which may be well to correct. Writing concerning another matter the editor of the *Boston Medical and Surgical Journal*, in a letter dated December 5, 1903, says, as regards the article on Francis Parkman, so courteously criticized by you:

"We are not in the least ashamed of having published it, and we can assure you that we have not been placed in a box thereby. On the contrary, we have no regrets whatever in having published it. As for the reproduction of the Parkman article in book form, we shall be very glad to have it appear as having been originally published in this journal."

The kindness and urbanity illustrated in your editorial toward me, I do not doubt, will move you to make amends to the editor of the *Boston Medical and Surgical Journal*. Toward brother editors one owes an especial consideration. Sincerely yours,

Philadelphia, Dec. 7, 1903. GEORGE M. GOULD.

SPECIAL ARTICLE.

BYWAYS OF MEDICAL LITERATURE.—XVIII.

STUDIES IN HUMAN NATURE.

PROFESSOR ELIE METCHNIKOFF, the distinguished Professor at the Pasteur Institute, who is probably one of the best known and certainly one of the best liked of living medicine men, has recently issued a book with this title "Studies in Human Nature" or an essay in optimistic philosophy. The original, of course, is in French, and while Professor Metchnikoff is a Russian, his French is idiomatically simple enough for any one who has a reading knowledge of the language. He dedicates the book to his wife and in closing the preface thanks especially his friend, Dr. Roux (who is, of course, the distinguished co-inventor with Behring of diphtheria serum), for having rendered his French more French. It is rather interesting to find the great pathologist, whose theory of phagocytosis has attracted more attention and been the source of more interest to scientists generally than perhaps any other medical theory invented in recent times, discussing what he calls the disharmonies of human nature and the possibility that there may be of making the disharmony concordant by a process of selective development especially under the influence and direction of men of science.

The third chapter of Dr. Metchnikoff's book contains a discussion of the possible Simian origin of man. Professor Metchnikoff does not seem to consider that this is as distant a possibility as many other biologists of the present time. He finds in the close relationship of the dentition of man and the apes and of the organization of their extremities and brain so many arguments for a relationship of descent. The resemblance between the vermiform appendix of man and of the anthropoid apes has for him much more than the force of merely a chance resemblance or an incidental analogy. The similarity between the placenta of the ape family and that of man and between the fetal development of man and of the anthropomorphic apes is for him an index of community of origin that is probably not very distant. His crowning argument, however, is the blood relationship between man and the apes, as that can be demonstrated by the fact that the serums from these two creatures have similarities as regards their hemolytic and precipitating powers which do not exist for animals farther apart from one another in the scale of life. This argument, of course, has only recently been exploited and so comes with apparently more force since the limits of its possible application are not as yet definitely decided.

Metchnikoff seems to be quite sure that a transmutation of species is quite possible and that this alteration need by no means necessarily involve a very long period of time or a very definite succession of minor modifications leading up to the complete differentiation of species. He cites the case of the famous lightning calculator, Jacques Inaudi, who demonstrates his skill in museums, etc., and who will be as familiar to most American medical men as he is to the French profession, since he has been on exhibition in this country, at least once, if not oftener. For Metchnikoff this case seems to show the possibility of the abrupt development of characteristics hitherto inexistent in the human species and that may possibly be transmitted and thus become the source of specific or even generic differences. The crux of the matter, unfortunately, is that usually these special peculiarities that make their appearance so unexpectedly in one generation are seldom transmitted to the next. While the Bach family has given birth in some two hundred years, it is said, to over forty distinguished musicians, it must not be forgotten that this is the only example of successive generations of a musical family on record, though there have been many other distinguished musicians besides the Bachs, and many musicians have had children besides the old baker, Vert Bach, who was responsible for the beginning of the musical proclivities of the Bachs.

Professor Metchnikoff finds not a few of the disharmonies of human nature in the organization and the exercise of the functions of the apparatus of reproduction. As a matter of fact he seems to consider that many of the drawbacks of present human life have their root in the disharmonies involved in exercises of the reproductive function. He has a very curious consideration of a practical character in this chapter that may be of interest to general practitioners. He suggests that in some cases of anemia doubtless the source or the toxic material which causes the destruction of red blood cells and consequently gives rise to chronic chlorosis, is due to a collection of microbes that find abundant nourishment in menstrual blood confined not behind an absolutely closed, but a very minutely patulous hymen. In these cases marriage and the rupture of the hymen with consequent free drainage of the vagina no longer furnishes this nidus for the growth of microorganisms and consequently there is the improvement of health not infrequently noticed in anemic young women after matrimony.

Metchnikoff's most interesting chapters from the social standpoint, however, are those in which he discusses the possibility of lessening the evils which result from the disharmony of human nature. The third part of

the book consists of the discussion of what science can accomplish for this purpose. Metchnikoff seems to be confident that an abiding faith in science will surely lead to great amelioration of the evils of existing conditions.

A rather interesting reflection at the present season of the year, when politics are so much on the tapis is found in the following paragraph: "In politics," Metchnikoff says, "the actual conditions correspond very closely to those of medicine in former times. Every individual of the male sex who has reached his majority is considered by the very fact to be sufficiently prepared for the exercise of all political functions, even the most difficult to be a rational voter, a sensible juror and the like. The only excuse for this state of affairs is the present infantile condition of social science. When sociology has become more advanced, the specialization comparable to that which has taken place in medicine will occur. It is only after this has happened that persons of years and discretion who shall have acquired extensive experience and be in the full maturity of their faculties, because of the integrity of their physiological condition will be able to render the greatest possible services to the society of the future. In this progress toward the true end of existence they will lose much of their liberty, but will gain in revenge a large amount of solidarity."

THE CONQUEST OF FIVE GREAT ILLS.

In *McClure's Magazine* for September, Mr. Cleveland Moffatt has an article on The Conquest of Five Great Ills, or The Great Work of the Pasteur Institutes throughout the world. The five ills that have been conquered are hydrophobia, diphtheria, lockjaw, bubonic plague and serpent venom. The demand of the popular magazines for articles of this kind, shows how deeply the public is interested in such advances in medicine. It would seem, however, that the articles with regard to them should come from medical men and not from regular literary contributors who may know how to write well enough, but who are sure to modify the facts of the case so as to make a better story.

This is what Mr. Moffatt has to say with regard to lockjaw: "As to lockjaw, the Pasteur Laboratory sends a steady supply of antitoxin serum that will prevent the outbreak of this disease, very much as hydrophobia inoculations prevent hydrophobia. In both cases it is true, the treatment is only preventive, not curative. But this is usually sufficient, since the danger is plainly indicated in advance. If by some sad oversight, hydrophobia does break out, it always kills just as it always has killed. But with lockjaw there is still a chance of saving life, even after an outbreak, by inoculating lockjaw antitoxin directly into the brain. The record of recovery is forty per cent."

We have just gone through our annual epidemic of tetanus in this country, and we are trying to impress people generally with the hopelessness of disease. There are certain milder cases of lockjaw or tetanus that run a chronic, or, at least, slow course, from the beginning and that are always hopeful, usually recovering without difficulty under any treatment. Certainly the physicians of this country are not ready to believe that forty per cent. of acute tetanus cases can be cured, even by intracranial injections of lockjaw serum. Our experience in this country with injections beneath the dura, has not veen very favorable and in Europe the practice has had a distinct setback since the first favorable reports were made. It is better that the public should have the truth in this matter, rather than have false hopes raised, that can not be fulfilled in practice. The difficulty lies in making clear to a non-medical writer the limitations of a method of treatment and the fact that very often when it is of most interest to medical men it is as yet only on trial.

A SOCIAL DISEASE.

A blind beggar was arrested not long ago in this city, and when taken before the magistrate on the charge of vagrancy and violating the city ordinance which forbids soliciting alms on the public streets, confessed that he did not have to beg for his support, as he was comfortably provided for, but that having nothing else to do he did it for pastime. He explained: "I only do it for pleasure. I can't see like other people and I would go mad if I sat in the house all the time. I do it to have something to keep me outdoors. I don't have to do it, as my brothers will take care of me, if I ask them to do so." This may seem a curious and paradoxical means of recreation to most people, yet there are many will sympathize with the blind beggar in his craving for something to do that would keep him outdoors. Some one said not long ago that the only justification for a housedog in cities is that it may serve the very beneficent purpose of tempting some elderly lady to take much more outdoor exercise than would otherwise be the case for the sake of a pet dog, who needs the air and the exercise so badly.

The New York *Times*, commenting on the incident of the blind beggar, says: "This blind man is a type of a very large class of persons not all mendicants by any means, but all incapable of other pleasure in life than that which comes from the close and often degrading pursuit of a painful occupation, after the necessity for concentrated toil has passed. There are in New York City some thousands of very wealthy men, who follow business for the same reason that the blind mendicant followed begging. They cannot read or think, or take pleasure in any form of intellectual recreation like other people, and if compelled to sit idle all day, would be at least profoundly unhappy. They perhaps have not the quality of brain to go mad in a conventional sense, or it may be they are already insane on the subject of acquisition and are incapable of any form of pleasure than that which is profitable in money returns. However, this may be, the case of many a merchant and financier is very closely parallel to that of the blind beggar, who could not be content, except when begging."

Such men are often the despair of their physicians, who realize the necessity for some change of occupation, and yet find it practically impossible to convince their patients of the advisability of taking the needed vacation. Usually the pretense is the necessity for their presence in order to secure the smooth-running of their multitudinous business affairs. The real reason is that the habit of a lifetime, the making of money, has become a fixed idea, a pathological entity of itself absolutely controlling mental processes. It is the new disease. The desire for the accumulation of money for which the subject has no real need and which he seeks for no good reason. We have thought that perhaps the presentation of the beggar's case and of the sensible discussion of it, from the standpoint of what is pathological in it, might be of service to the practitioner in some of these difficult cases. Anyhow the case deserves a place in memory. The *Times* very appropriately adds that "the individuals afflicted with this new social disease are commonly the objects of misplaced sympathy. No doubt in their way," the editor concludes, "they are as happy as other people."

PHYSICIANS AND LITERATURE.

The distinguished literary member of the English medical profession who was honored by being raised to knighthood on the occasion of the coronation, Sir Arthur Conan Doyle, is announced as preparing new triumphs for himself by pursuing once more the adventures of

Sherlock Holmes. Novel readers generally consider that Dr. Doyle had effectually disposed of Sherlock Holmes by having him go over a precipice in the Alps. Fiction is stranger than truth in this case, however, and the physician-novelist is able to accomplish the impossible and bring his hero to life once more. This is one of the advantages of romance over life. So many disadvantages in fiction have been pointed out of late years, especially for instance, the fact that the deaths exceed the births so much in novels that it is only a question of a comparatively brief time, until the stock of available heroes and heroines for romance will die out that it is a pleasure to find romance has some great compensations in its favor.

Dr. Doyle is announced as interested in another phase of reproduction besides his literary work. He has bought all the patent rights on a process for reproducing marble busts by a method resembling the pantograph as applied to the enlargement of pictures. It would seem as though subsidiary occupations were to prove more lucrative than the mere practice of medicine. One is forcibly reminded of Dr. Oliver Wendell Holmes' expression with regard to literary men in which he so charmingly improved upon Samuel Taylor Coleridge. Coleridge had said "A literary man should have some other occupation," to which Oliver Wendell Holmes added "and, as far as possible, he should confine himself to the other occupation." As is well known, Dr. Holmes did not follow his own rule very faithfully. If we are to judge from recent successful invasions of the literary field by physicians, of which there are now many notable examples, the form of the expression will, for twentieth century use, have to be modified into something like the following: "All physicians should try their hands and make use of their medical experience in adding to the world's literature. If it pays, they should, as far as possible, confine themselves to the new occupation, since it brings not only money, but glory." If the new maxim will only help to deplete somewhat the overcrowded ranks of the profession we wish it all possible mandatory influence.

HOW MUCH TO EAT.

J. M. Barrie, who seems to be able to do anything, has just produced in London a successful comedy, of which the hero is the stomach. Probably no other dramatist alive could handle such a topic, full as it is of widespread human interest. The American world especially now reeks with dyspepsia cures: No breakfast, no lunch; meat diet, vegetable diet; few meals, many meals; regularity, variety; small quantities and large. A man may cut his allowance down to steak and toast, and still have indigestion. He may feed on lobster salads and ale at midnight and prosper grossly. A German alderman advised us, many years ago, to cure all interior problems by two matutinal mugs of beer. We were turning over the *Autocrat* a day or two ago, brooding upon how human standards change. The poem therein called "Contentment" has for its comic idea luxurious wishes masquerading as simplicity. "A ruby, and a pearl, or so, will do for me; I laugh at show." How is dinner treated on this principle? By assuming that *three* courses are extravagant. "Plain food is quite enough for me: Three courses are as good as ten.' That, in 1857, was as if to-day we should say "Ten courses are as good as twenty." The allegation that "man wants but little here below" has to be interpreted in the light of change. It may at least be assumed that, whatever he gets, it is less than he wants. As Holmes puts it, "I only ask that Fortune send a *little* more than I can spend," which is a large order for Fortune. Luxury, now so dominant with us, has, among its other consequences, led to gross overfeeding, in the attempt to get amusement out of meals, but just how much and what to eat, in individual cases, remains one of the questions which often baffle the most successful doctors. —*Collier's Weekly.*

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Section on Ophthalmology.

Stated Meeting, held Thursday, November 5, 1903.

The President, Andrew H. Smith, M.D., in the Chair.

Lesions of the Eye, which Occur in the Course of Diseases of the Heart, the Blood-Vessels and the Kidneys.—This was the paper of the evening and was read by Dr. Charles Stedman Bull, who said that the intra-ocular circulation furnishes a visible picture of the condition of the general circulation and is thus of great diagnostic value in diseases affecting the circulation. In anemia for instance, the papilla is apt to be much paler in color than normal, and if during the ophthalmoscopic examination even gentle pressure is made upon the globe, the veins and arteries are emptied. Spontaneous hemorrhage from the intra-ocular vessels is prone to take place under these circumstances, while on the other hand retinal hemorrhages from high tension of the arterial circulation occur quite often and are followed by the appearance of white patches showing traces of the degenerative process by which the effused blood has been reabsorbed.

Central Scotomata.—Large blind areas occurring in the center of the field of vision are usually a sign of the rupture of the arteria centralis retinæ. Such a rupture of this artery may, however, occur within the nerve sheath a considerable distance back of the eye, without producing any visible change within the eye. In these cases the central scotomata are at first hard to explain. When aortic insufficiency exists there is a pulsation of the retinal arteries easily noticeable with the ophthalmoscope and an alternate flushing and paling of the disc may be readily noted in advanced cases. This corresponds with the capillary pulsation which is noticed in other parts of the body, but which occurs on the eye ground before it is visible elsewhere, and thus becomes a valuable early diagnostic sign of the insufficiency of the aortic valve. With stenosis of the aortic valve such a pulsation is absent, so that this may constitute a differential diagnostic sign between the conditions.

Venous Congestion.—In many forms of heart disease a general venous congestion occurs, and this is visible also in the dilated and tortuous veins of the retina. Such general venous congestion may occur particularly in mitral heart disease and may in advanced cases cause a pulsation of the retinal vessels. Changes may be noted, however, in the conformation and function of the retinal vessels when there is no patent heart disease or true disease of arteries, though in these cases there will usually be found some latent disease of the heart or kidneys. Endocarditis in its various forms may produce symptoms on the eye-ground which usually are in the form of emboli with subsequent thrombosis. In rheumatic endocarditis it happens not infrequently that emboli find their way into the retinal vessels, causing temporary blindness over some portion of the field of vision. This form of endocarditis is benignant in its effects, and usually recovery is quite complete. Malignant endocarditis, however, as might be expected from the fact that it is a septic condition gives rise to emboli which set up septic processes and produce serious consequences. An embolus of the central artery of the

retina is always a serious condition, since this is a terminal artery, and the collateral circulation does not make up for the hindrance to the blood-current. This may in certain cases be the first sign of endocarditis. The patient usually becomes totally blind in the eye, and if the circulation is interrupted for any length of time, the retina takes on a grayish color, and as the result of nerve degeneration, the blindness becomes permanent. If only a branch of the central artery is affected the opacity is limited, but the blindness may be permanent over this area. If severe cases of arterial degeneration, miliary aneurisms may be noticed on the eye-ground and are of pathognomonic significance. These occur, as a rule, only in people beyond middle life in whom there are advanced arteriosclerotic conditions. In old patients, however, they are a warning of the possibility of the rupture of an artery in the brain, and patients with such signs should be told of the danger they are in from apoplexy. Sometimes when retinal degeneration is visible in the eye-ground the carotid arteries are so thickened as to be quite palpably degenerate. The underlying pathological condition in these cases is usually syphilis. When nervous lesions exist causing deviation of the eyes, the direction of the deviation may be pathognomonic of the position of the lesion. If the deviation of the eyes is toward the affected side the lesion is in the pons. If the deviation is away from the affected side, the lesion is above the pons. With regard to thrombosis of the venous sinuses, the symptoms in the neighborhood of the eye may be of more diagnostic significance than other physical signs. Usually there is paralysis of the oculomotor nerve with consequent inability to move the eye. If the conjunctiva and soft tissues in the neighborhood of the eye are affected by edema, then the lesion within the skull is not far behind the eye itself. This usually indicates the thrombosis of the lateral sinus.

Albuminuric Retinitis.—In acute nephritis very often the first sign of the occurrence of infection of the kidneys is the presence of edema of the eyelids. In severe cases this may even lead to chemosis, that is, edema of the ocular conjunctiva. Affections of the iris often occur in kidney trouble. Changes in the choroid are also noticed, commonly, however, in conjunction with arteriosclerosis accompanying the kidney trouble. The ocular muscles are said not to be affected in pure kidney disease. When such symptoms occur, there are usually hemorrhages into the nerve roots or the nuclei from which spring the nerves that supply the various muscles.

Prognosis.—When nephritis gives symptoms in the eye, especially when chronic nephritis causes retinal degenerations, the prognosis is always bad, but ameliorations of the condition are not infrequent. It is sometimes asserted that death will take place usually within two years after patches of retinitis albuminuria are discovered. This is not an absolute rule, however, and refers rather to dispensary and hospital cases who are very seldom in a position to take that care of themselves necessary in order to prevent progress of the ravages of nephritis. When the lesions are very marked, death will usually take place within a year. In 62 per cent. of Dr. Bull's cases, the fatal termination came within six months. Seventy-five per cent. were dead at the end of the year. All of the patients that could be traced were dead at the end of two years. Other observers say that about six per cent. will be alive at the end of two years. The importance of this condition is readily understood then, and the characteristic appearances should be familiar to every one. Usually there are yellow, stellate patches around the nerve ending. These are frequent near the macula lutea, and especially between that spot and the disc. Edema of the retina sometimes occurs, leading to folds in this structure and consequent detachment with loss of vision. The primary change, however, is in the blood-vessels, and all other changes are secondary. As the retinal vessels are terminal arteries, the collateral circulation does not compensate for their deficiencies, hence the outspoken character of the lesions. Retinitis albuminuria is usually bilateral, but this does not necessarily mean that it must occur simultaneously, nor that both retinæ shall be affected to the same degree. The very curious fact is that vision is not affected always to the extent that might be expected from the ophthalmoscopic picture. At times, very few lesions can be seen, yet there is great disturbance of vision.

Retinitis and Pregnancy.—If albuminuric retinitis occurs during the early stages of pregnancy, labor should be induced. Where there is a distinct amount of albumin in the urine, and the characteristic signs on the retina, it is worse than useless to wait, for abortion will probably take place anyhow, but at a time when neither mother nor child can be saved. If there are changes on the retina in the latter part of pregnancy, then this rule does not hold. For instance, during the last month of pregnancy, there should be no question of the production of premature labor. If the retinal symptoms develop before six months, however, the safest course is to have labor induced. This depends, in Dr. Bull's experience, somewhat on the condition of the arteries. If the arteries are in good condition the albuminuric retinitis of pregnancy is not dangerous. If the arteries in the eye-ground, however, look like white cords and the capillaries are blocked, then the nerve and its distribution throughout the retina will surely atrophy, if the kidney insufficiency is not relieved by removal of the fetus.

Uremia.—The condition of the eye is extremely important in chronic interstitial nephritis, because the arterial condition can be so well recognized here. When there are severe lesions on the eye-ground, especially if there are exacerbations of the ocular condition, they must be accepted as a warning of the danger of the development of uremic intoxication. The onset of uremic coma may thus be anticipated and measures taken to prevent it, or its occurrence put off, to see that the patient is put in proper condition for its treatment, so that relief may be afforded without delay.

Dr. F. P. Kinnicutt, in opening the discussion on Dr. Bull's paper, said that the occurrence of edema and of other constitutional symptoms during kidney disease, are often attributed to toxemia consequent upon kidney insufficiency, but there is some difference of opinion in the matter. The main question is whether the retention in the blood of excrementitious products brings about the toxemic condition, or whether, as a consequence of the retention of such products, an abnormal metabolism was set up, which of itself produced toxic substances.

There is in the system under conditions of kidney insufficiency an accumulation of urea and creatinin and other such products, that are not simply the result of retention, but must be due to increased production. Such toxemias may produce amaurosis. This occurs typically during severe acute scarlatinal nephritis. At times, when there is rapid diminution of the amount of urine passed. In these cases the point of selection of the action of the toxins on the nervous system is the visual tract. Rapid recovery is the rule, but the subsequent history of such cases, has not been followed in a sufficient number of patients to enable authorities to judge as to whether there may not be a deteriorating influence on vision afterward. The neuroretinitis of chronic interstitial nephritis is an index of an advanced condition of kidney degeneration and usually means a fatal issue within two years. The kidney trouble may

date back over many years, but once it begins to affect the retina the end is not far off, as a rule. There are exceptions, however, which indicate that more careful study will have to be given to this question before absolute prognosis can be formulated. Dr. Kinnicutt cited some illustrative cases in which, notwithstanding the appearance of neuroretinitis, patients subsequently recovered their vision and remained for many years without any further symptoms.

Illustrative Cases.—One patient, at the age of forty-eight years, noticed that his vision was much dimmer than it had been. What first called his attention to this fact was his inability to see well enough to mend a bicycle tire. He was heating a wire for this purpose, but when the wire became hot, the dimness of vision incident to watching the flame lasted so long that before he could use it for the purpose intended, the wire became cold. Observation with regard to his vision showed that in the right eye lights were seen edged with red, and there was a spot in his vision. Albumin was discovered in his urine, and the case looked very serious. He recovered much of his vision, however, as a consequence of careful treatment, and has had no further disturbance of vision and no deterioration of his general health now for about eight years.

Rapidly Fatal Cases.—On the other hand, Dr. Kinnicutt's experience has shown him that the occurrence of albuminuric retinitis may be followed by a fatal termination in a comparatively short time. In a recent case, the first symptoms of kidney trouble were digestive disturbances followed by paroxysmal dyspnea less than six months ago. Bilateral neuroretinitis developed in the course of the affection. In less than six weeks after the first symptom the patient died. It must not be forgotten that diabetes may also cause retinal lesions, and that a complication of diabetes and nephritis is not unusual, especially toward the end of diabetes. In a recent case under Dr. Kinnicutt's care, the patient's mother had died of diabetes, but notwithstanding the presence of a carbuncle some five years ago there was no suspicion of any glycosuria in her case, until eye symptoms developed.

Pathology of Albuminuric Retinitis.—Dr. Ward A. Holden said that the course of pathological lesions in the eye are not always easy to trace, but that albuminuric retinitis seems to begin with diffuse edema of the retina and the optic nerve. This leads to disturbance of the blood-vessels, and before long hemorrhages develop. During the course of the degeneration of the hemorrhagic patches white spots develop. When hemorrhages occur near the macula lutea they are small in size, and are more frequent producing the speckled appearance familiar in so-called albuminuric retinitis. It may be said at once that there is no true neuritis and no actual retinitis present. The edema that occurs first is due to serous exudation from the blood-vessels, and this follows the course of the nerve fibers. The hemorrhages that follow are not due to rupture of the arteries, but to diapedesis, because of the outwandering red blood-corpuscles through the diseased vessel walls. The white patches that develop subsequently are due to fatty degeneration of these red blood-corpuscles. Capillary hemorrhages occur from the deep retinal capillaries which have a tendency to converge toward the macula lutea, hence the characteristic picture presented in these cases.

Venous not Arterial Hemorrhage.—Dr. E. Gruening said that notwithstanding all the investigation made into diseases of the eye, we, as yet, have comparatively little definite information with regard to many of the affections whose symptoms appear upon the eye-ground. Dr. Gruening has never seen arterial hemorrhage in the eye, unless the arteries were very much diseased. Hypertrophy of the heart alone is never sufficient to cause rupture of the arteries. Venous stasis within the eye is rather easy to recognize with the ophthalmoscope and much can be done to correct it by modification of intra-ocular tension by means of properly directed massage.

The Eye in Apoplexy.—Dr. John Winters Brannan said that the eye symptoms of apoplectic conditions are anomalous and often fail to be of diagnostic significance. This is illustrated very well by two recent cases that have been under his care. In the first, a married woman of some forty years of age, who had borne seven healthy children but had no serious illness, was found to be suffering with some very slow-running diffuse nephritis. Casts and albumin were present, though there was no enlargement of the heart. She became unconscious in her bathroom one day, and evidently suffered from a slight apoplectic seizure, for after her unconsciousness passed off, hemiplegia of the left side remained. She recovered completely from this. Notwithstanding the presence of albumin and casts, there were no eye symptoms at any time. In a second case, a woman, also of some forty years of age, suffered from an apoplectic stroke which affected the right side of the body with the left side of the face and a loss of vision on the left side. The eye muscles on this side were also affected. While she recovered from the hemiplegia of the body and regained control over her facial muscles, the palsy of her eye muscles continued. The presence of albumin and casts in these cases must not always be taken as indicating that a nephritis is at work. Nearly always after apoplexy, casts and albumin are found in the urine, but they pass away after a few days and it would seem that their presence was due to the shock rather than to any actual kidney lesion present before the apoplectic stroke.

Difficulties of Diagnosis.—Dr. T. R. Cooley said that while there is a voluminous literature with regard to intra-ocular disease and especially with regard to the change produced in the eye as a consequence of affections of the arteries, the heart and the kidneys, there has been very little real advance, and science is almost tediously slow in its progress. With regard to so-called diffuse senile changes which occur in the retinal vessels, Dr. Cooley has always found it extremely difficult to differentiate them with assurance from changes due to syphilis. Even in old persons it is important to make inquiries with regard to a possible syphilitic history. If they are syphilitic much can be done to relieve them by mixed treatment. In a recent case under Dr. Cooley's care, the age of the patient, over sixty-five years, seemed to render it unnecessary to inquire with regard to syphilitic history. Yet the condition observed on the retinal arteries proved eventually to be due to syphilis. It is curious to realize that there may be large amounts of albumin and casts in the urine without any albuminuric retinitis. On the other hand, occasionally small petechial hemorrhages occur in the eye, which seem to indicate the presence of Bright's disease, yet no albumin can be found. In some of these cases Dr. Cooley has seen Bright's disease develop later. The appearances in the retina then must always be considered suspicious, even though no albuminuria can be demonstrated. With regard to the albuminuric retinitis of pregnancy, it is important not to give a bad prognosis until the case has run its course. Dr. Cooley has seen a retinitis of pregnancy with detachment of both retinæ, followed by reattachment and excellent vision after the induction of premature labor.

Ocular Emboli.—Dr. Knapp said that Professor Billroth, of Vienna, was the first to suggest, in one of his lessons in pathology, that the occurrence of embolism and the consequences of the lesion might be studied in the only set of visible arteries, namely those in the eye.

Within three days after he made this suggestive remark, a case of embolus of retinal vessels was studied and described in one of the clinics of Vienna. This is of itself the best proof that the condition of the vessels of the eye may well be taken as an index of the vascular system throughout the body.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, held Thursday, December 3, 1903.

The President, Andrew H. Smith, M.D., in the Chair.

The Problem of Keeping New York City's Streets Clean.—This was the title of the paper of the evening, by Dr. John H. Woodbury, Commissioner of Street Cleaning of New York City.

Former Conditions.—Dr. Woodbury gave a series of stereopticon pictures in which he showed the condition of New York streets when he took charge of them two years ago. Hester Street, at that time was a crowded thoroughfare constantly filled with a compact mass of people, crowded around the push carts, so that it was impossible to properly clean it. Rivington Street was the same way. Along the curbs of both these streets there were open market carts, adding further by their refuse to the difficulty of cleaning the streets and keeping them clean. Dr. Woodbury dwelt on the fact that streets were the public highways and that the abuse which allowed push-carts in large numbers on them was an unwarranted diversion from the true purpose of maintaining a thoroughfare.

Establishment of Fish Market.—On Rivington Street especially, the nuisance of the push carts became greatest, because here all the fish food was sold for the neighboring streets of the crowded lower east side. Fish in all stages of decay were offered for sale in the midst of a dusty, dirty thoroughfare, and the waste material from the sales inevitably found its way to the street to add further to the noisomeness of the conditions. In order to do away with this nuisance and make the maintenance of clean streets in this neighborhood possible Dr. Woodbury established Rivington Street Fish Market beneath one of the arcades of the new Williamsburg Bridge. At first it was impossible to make the foreign-born peddlers understand that this new market was intended for their use without any payment. After a few of them had experienced what was the real purpose of the change the others flocked in, and now it is not so difficult to keep the streets clean and clear in the neighborhood. Dr. Woodbury insists that other such improvements must be made in other parts of the city, and that markets for other food materials must also be established. Many food materials have been sold from these push carts on the open streets and the number of germs present in the air in these crowded thoroughfares makes this eminently undesirable. Bread, cakes, biscuits and candies are exposed, and various forms of delicatessen. The children are likely to suffer most from such street-exposed food, as they are least resistive to bacterial invasion, and are less likely to be squeamish about what they eat. Thus the matter of street cleaning becomes very important in the summer time for the maintenance of the public health. It must not be forgotten that a city's health is the function of its most unhealthy portions, and that the slums of the lower East Side may easily prove a source of infection even for upper Fifth avenue.

Street Cleaning Methods.—The Commisioner of Street Cleaning must maintain the cleanliness of 1,076 miles of streets. In the more crowded portions of the Borough of Manhattan, particularly, many of these streets must be cleaned twice a day. Wherever the old block pavement remains the only possible way of securing cleanliness is by the man with the broom, the shovel and the bag. In very crowded streets the same thing is true. It is impossible to send a street-cleaning machine through Fifth avenue in the busier portions of the day. The employment of so many men requires organization and esprit de corps. The men employed must be treated as if part of a military company and discipline maintained by military methods. So much was acomplished in establishing this system by Col. Waring, however, that now it is not difficult for his successors, if they have the good will, to maintain it. It is important that asphalted streets should be thoroughly cleaned, in blustrous weather particularly, as the dust from them is likely to be even more noticeable than from rougher paved streets. The dust represents to the medical men a collection of many kinds of germs. For cleaning asphalt, when the temperature is above 50°, the only thing that is effective is a stream of water delivered at high pressure over the surface of the pavement. For this purpose street-cleaning apparatus in which water can be kept at a pressure were invented by the French, and are now in use in this city. Several of them were exhibited in pictures that delivered a stream of water under 20 atmospheres of pressure. This forces the water toward the gutter line and thoroughly cleans the street. Water wagons are also employed in front of the tank of which there is a gas engine, by which a pressure of 100 atmospheres can be secured in the water tank. This cleans asphalt very effectually. So far a lack of sufficient appropriation for the purpose has made it impossible to secure more than a few of these.

The Ash-cart Nuisance.—Up to the present time the loading of ash-carts and the carting of ashes along the streets in the open carts has been one of the great city nuisances. Clouds of fine dust were blown about to settle on everything, to be raised again by the wind and be a continuous bother and irritant for respiratory passages. On a March day a goodly proportion of the ashes seemed to get back into the air. The attempt to abate the nuisance by means of a cloth cover proved a failure. For a time then a wooden cover was employed, beneath which the dumping of the ashes could be secured. As a result of various trials and experiments Dr. Woodbury has finally adopted a large steel wagon completely covered, and with a roll-top desk opening. This not only abates the nuisance of dust, but gets rid of the unsightliness of the old vehicle.

Disposal of Garbage.—Under the old system of carrying the garbage out to sea in dumps and scows there were many serious objections. Much of the material was carried back into the next tide to decorate the bathing beaches in the neighborhood of the city, and be not only a nuisance, but a source of danger to health. The floating material from these scows made the waters near New York unsightly, and the solid material in the opinion of experts was sure eventually to create a bar just at the entrance to the harbor. Under the system introduced by Dr. Woodbury these objections are all done away with. All the garbage material contained in the ashes is taken out and the ashes are used for filling in near Riker's Island. Already a large amount of new ground has thus been made which will eventually be very valuable. In the meantime the dumping scows, especially those of the Delehanty pattern, are held in reserve for emergencies in case the present system should prove insufficient for some special reason, as for instance if a fire or some other serious unforeseen accident should cripple the department's resources.

Classifications of City Waste.—There are three classes of city waste that must be disposed of, each of which requires some different treatment. These are

garbage, rubbish and ashes. By garbage is meant the kitchen waste of houses and hotels, commonly called swill. By rubbish is meant all the household material that, being no longer of use, is left to the street-cleaning department to dispose of. This includes beds, bedding, old furniture, old trunks, boxes and receptacles of various kinds, of different degrees of uncleanliness, and all the broken material of the household. Under ashes is included of course a certain amount of broken material, tin cans and other articles that do get inevitably into the ash pans.

Garbage Disposal.—All the swill material is now taken to Barren Island. This is all organic and extremely offensive material. Here, by means of a reduction process, the watery material and gases are taken out of it, and a compressed, inodorous residue obtained after the digestion of all the organic material. In order to prevent the nuisance, formerly so marked, all ill-smelling smoke from the Barren Island plant and the gas from the digesters are thoroughly washed before being allowed to escape into the air. This unfortunately leads to the loss of an immense amount of valuable ammonia. The sweepings of streets and other organic material constitute the best of manure and is now sold in quantities to many parts of the country. This forms a constant source of revenue.

Rubbish.—This material often contains articles that may still prove useful and always has in it an immense amount of valuable material for fuel. The handling of it is no longer not only not an expense, but is a source of revenue to the city, since a contracting company more than pays for the collection of it for the permission to take out of it any material that may seem of value. The residue is now being used for heating purposes and will surely prove of value. Even after the rubbish has been burned the residual ash has such a high potash content that it is an extremely valuable material.

Disposal of Ashes.—On February 14, 1902, the department began to dump ashes into an open crib near Riker's Island for the purpose of increasing the size of the island. Sixty-three acres have so far been reclaimed from the ocean very effectually, though certain problems have had to be solved that were unexpected. The East River is deep and clear, and has little mud but a strong tide. The setting in of this tide makes work difficult at Riker's Island, and on one occasion, at least, caused considerable damage to the construction work there carried on. The distribution of ashes and the leveling of new-made ground is confided to convicts, the labor being cheap, but quite as poor as it is cheap. The convicts employed are mainly the tramps and vagrants. Belt conveyances are employed to distribute the ashes at a distance from the barges, and so far there has been excellent results obtained from them.

Street Bacteriology.—By exposing agar plates at varying heights from the ground, Dr. Woodbury succeeded in getting bacteriological maps of the atmosphere in the most thickly settled district. Hester, Rivington and Oak streets gave so many bacteria after thirty minutes' exposure that not more than fifteen minutes of exposure could be employed and even then many hundreds of bacterial colonies developed on each plate. Exposures of the same kind made on upper Fifth avenue and Madison avenue gave very few bacteria and only a few molds. Pell Street was found reasonably clear of bacteria, though containing a number of molds in the atmosphere. John Chinaman is not unclean, though the presence of organic products in his neighborhood when living in thickly settled districts may invite the presence of molds. Mulberry Street, in the Italian quarter, gave an uncountable number of colonies after fifteen minutes' exposure and a single hour's growth in an incubator. Washington Market proved to be nearly in the same condition and the photograph of the plate taken shows what danger there is in the exposure of moist food products in the air under such circumstances. Many food materials are almost as good nutrient media for bacteria as agar is. As a rule the number of bacteria are directly proportional to the denseness of population in a given neighborhood. As a rule, too, these thickly populated districts fairly swarm with children. This adds to the danger to the health of the individuals because the population contains such a large proportion of the young non-resistive elements. It is not an unusual thing on the lower East Side to have 20 families to every 25 feet street front, and these 20 families will number at least 50 children among them. This gives a better idea for the necessity of cleanliness in these thickly populated neighborhoods and for the special vigilance of the Street-Cleaning Commissioner, if the Board of Health is not to have its work greatly added to.

Utilization of Rubbish.—An experimental plant for the separation of whatever useful materials there might be in the rubbish collected in the street-cleaning departments and the burning of all inflammable material has been established at Forty-ninth Street. This furnishes enough heat units to supply lights for the stable at Fifty-second Street, leaving a large surplus of heat to be wasted. The bill for lighting this stable before was nearly $6,000 annually. This is a direct saving. It formerly cost the city about $500 a week to get rid of this material, while now the revenue from those who have the opportunity to select whatever useful material there is in it is $250 a week. When to this is added the new saving in the matter of lighting the city will find this material an important source of revenue.

Experimental Work.—This is only experimental as yet, but there is no doubt that on a large scale it will prove even more lucrative than has been represented. The plant is situated on a dock over the river, it is inefficient according to our present scientific knowledge; it is not well located; it is not industrially well arranged, yet at the present time it is actually saving the department over $10,000 a year. This gives some idea of how much can be accomplished when the problem is approached scientifically. It is surprising how much of the waste material can be used over and over again. Even the tin cans that form so large a part of the rubbish collected by the street department are now shipped to a factory on Long Island, where, by means of heat, the solder and tin are melted off to be again utilized. Even the steel plates are not entirely useless and are used for roofing purposes and other objects.

Problem of City Lighting.—One of the largest items of expense which the city government has at the present is that of lighting. There is no doubt that much of this can be supplied by plants erected in connection with the rubbish disposal plants. As a consequence of this, too, the boxes and barrels, the floating material of various kinds that formerly used to be taken down the bay and, after dumping in the ocean, floated back with the tide to be scattered over the beaches, making an unsightly condition and a very unhealthy state of affairs for the bather, can be destroyed under absolutely aseptic conditions and their usefulness as fuel is easy to understand. Of course, during the two years that Dr. Woodbury has been in charge of the department only a beginning of this scientific treatment of refuse has been instituted. The new administration, however, will find this beginning of such a nature that they can easily raise a superstructure of important retrenchment for the city within the department of the Commissioner of Street Cleaning.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Section on Clinical Medicine and Surgery.

Stated Meeting, held Friday, November 6, 1903.

A Study of 337 Cases of Enteric Fever in Children.—Dr. S. S. Adams, of Washington, D. C., reported his series of cases from the Children's Hospital of Washington. The clinical features of enteric fever in children have been variously interpreted, the typhomalarial cases having been at one time excluded and at another included under this diagnosis. Dr. Adams' experience has led him to doubt the immunity of children to typhoid fever, which is claimed by some authorities. The majority of his cases occurred in the late summer months, and they differed only in degree from the adult cases. Epistaxis occurred in 50 per cent. Of 210 cases, 31 had hemorrhage, and 18 died. Mental changes were often present, one case of fatal hemiplegia and 6 of posttyphoid insanity being noted. In 75 cases the diazo-reaction was positive and in 4 cases (all fatal) cancrum oris occurred. Thirty-seven cases showed typical lesions post mortem, and in 11 there were perforations. The fever was usually remittent in type and fell by lysis. Rose spots, though often observed, were less common than in adults and bed sores were seldom seen. There were 32 relapses in the series and of 70 cases in which the Widal was tried 50 were positive. The mortality for the whole series was 14.2 per cent., but of the cases occurring since 1899 the mortality was 10 per cent. The general management of the cases was, in recent years, about the same as that of adult cases. Hydrotherapy was used quite freely and intestinal antiseptics discarded as useless after fair trial. During the period when the Brandt treatment was used the mortality was about 11 per cent.

Dr. Atkinson said that in the typhoid fever of children the absence of rose spots, the presence of constipation rather than diarrhea, and the mild course are the most striking features. The temperature is usually easy to control and should be treated with baths and not with antipyretics.

Dr. Osler said that there can be no question of the immunity of *young infants* to typhoid fever. Dr. Griffith, some years ago, could only find 300 odd cases in the whole literature. It must be remembered that children's hospitals, like the one where Dr. Adams' series of cases was treated, function as "dumping-grounds" for the community, and the worst cases, therefore, occur in them. This explains the relatively high hospital mortality. Dr. Platt mentioned the features of about 90 cases of typhoid fever occurring in a children's hospital in Baltimore. The treatment was expectant, no antipyretics were used, and the cases were, as a rule, mild. Constipation was almost always present. A case of typhoid fever was reported in a seven months' old child taken from a mother with typhoid. Dr. Apt's series of 200 cases of typhoid in children was reviewed. One hundred and ninety-eight gave a positive Widal, 55 showed rose spots, 2 had perforation, and 10 per cent. relapsed. The general opinion was that the typhoid fever of children in Baltimore is milder than the disease in other cities. Dr. Adams said that his series included every death during the course of the fever, no matter what the cause, 4 cases of undoubted typhoid having died of tuberculosis. Severe cases are undoubtedly seen, but so long as the fever remains within bounds and mental disturbance is absent little treatment is needed.

The St. Louis Hospital, of Paris.—This hospital, founded by Henry IV. in 1657, is now a great medical center for the study of syphilis and skin diseases. Four things make this true—First the enormous number of patients, second the character of the men on the hospital staffs, third the liberal laboratories, and fourth, the splendid museum and library. The wonderful St. Louis collection of models of skin diseases is of great use to any one interested in this department of medicine. All of these are life-like, but the models of the various forms of drug rashes and of the erythemas are particularly good. The great Foulard library, with its perfectly complete collection of works in all tongues, dealing with syphilis and skin diseases, is easily accessible to students.

Congenital Dislocation of the Hip.—Dr. Platt showed a case of this affection. The patient was a girl of ten years, who, a few years ago, had shown only a slight disability of the hip. This had since become much worse and telescoping of the limb had occurred. The case showed two characteristic features of congenital dislocation—free rotation of the head, the trochanter remaining almost stationary, and the failure of the lumbar spine to move with any motion of the affected leg. The ligamentum teres was probably absent in this case and the open operation was advised by Dr. Platt.

Meeting held November 20, 1903.

Blastomycetic Dermatitis and of Epithelioma of the Nose Cured by X-ray Treatment.—Dr. Gilchrist exhibited this case.

Treatment of Bow-Legs and Knock-Knee.—This paper was read by Dr. R. T. Taylor, who said that in the treatment of rachitic deformities braces have been found expensive, tedious and uncertain. Three operations may be done: Osteotomy, osteoclasia and epiphyseal lysis. The real cause of these two conditions is an abnormal curve of femur, tibia or both, and not a lengthening of the internal condyle as the text-books say. The aim of the treatment is "centric correction"—that is, an operation performed at the apex of the deformity. Osteotomy has given good results in aseptic cases, but infection has occurred and has caused serious trouble. Osteoclasia is quickly done, is free from the dangers of sepsis, never results in delayed union and leaves a hinge of bone which keeps the fragments together when healing. A new osteoclast working on the lever principle was presented. It was claimed to accomplish its purpose almost instantaneously, and therefore to require little anesthesia.

New Method of Recording Rotation in Lateral Curvature of the Spine.—This subject was also presented by Dr. Taylor. The patient was placed on the stomach, a yard stick laid over the back with the middle point at the spinous process of the vertebra, and the angle made by this stick with the line of the floor measured by means of a right-angled triangle graduated for the purpose.

Dr. Platt, in the discussion, said that after the fifth year the bones harden and braces are useless, but good results are obtained before this age. Later operative procedures must be resorted to. Osteotomy is usually the preferable operation, and must always be done in the sabre-shaped deformities with forward bend. Many cases of bow-legs are seen in children and few in adults and probably nature cures many of these patients.

Dr. Taylor said that knock-knee may be outgrown, it is true, but one cannot prophesy in any given case, and so have no right to trust to it. Epiphyseotomy, though mentioned as an operation, is really impossible. Blanchard tried it in several cases, but he always got a tear of the lateral ligaments of the knee and of the biceps tendon.

Brisement Forcé Treatment of Clubfoot.—This was the subject of Dr. Sidney M. Cone, who said that

modeling methods in orthopedic surgery are based on Wolf's principle, that the structure of bone is modified by the function which it has to perform. Wolf was a German engineer who became a surgeon, studied carefully the mechanics of bone deformity, and left very careful photographic records. In his treatment the affected limb is put up in plaster and molded while this is soft. Two weeks later the position is further corrected by a second molding, and by repetition of this process the required position of the limb is finally obtained.

Dr. Taylor, in discussing this paper, said that Wolf's work ought to lead to the abolishment of the pernicious treatment of clubfoot by operative removal of bone.

Dr. Platt said that many surgeons do remove bone to correct this deformity, and the results are good, though, of course, not perfect. The procedure is, however, a rational one.

Dr. Cone said that brisement forcé ought to be used preferably in young cases, but Lorenz tried it first in a man of twenty-eight years with perfect results.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held at the New York Academy of Medicine, November 9, 1903.

The President, Andrew H. Smith, M.D., in the Chair.

The Treatment of Lobar Pneumonia.—A discussion of this subject constituted the scientific business of the evening. It was opened by Dr. Glentworth R. Butler. He said there were few diseases in which the prognosis is so variable in the individual case. Recovery will occur in some under any circumstances; others prove fatal no matter what treatment is adopted, and in a third group the outcome is apparently dependent upon the timely and energetic use of accepted therapeutic methods. Yet the general mortality varies little from decade to decade, while the incidence of the disease, in consequence, it is believed, of the prevalence of epidemic influenza, is increasing. There is as yet no specific for lobar pneumonia. The statistics regarding therapeutic methods are peculiarly liable to error because of great natural variations in the mortality rate which are largely dependent on three conditions: (1) age; (2) the presence of previous degenerative or other disease, particularly of the heart and kidneys; and (3) the varying virulence of the infective agent. There is no unanimity of opinion respecting the use of antipneumococcus serum, and in all probability the specific treatment for the disease will be found in the discovery of an antitoxin which will counteract the toxemia of the disease, although it is contended by some that lobar pneumonia is not a bacterial unity and may be caused by other pathogenic organisms than the pneumococcus of Fraenkel. A common fault in considering the treatment of this disease lies in an insufficient appreciation of the very considerable natural variations in the duration of the attack. As it is quite impossible to forestall the probable duration of the individual case, the claims of certain over-enthusiastic observers who profess to have aborted the disease must, perforce, receive the Scotch verdict, "Not proven." Owing to the variable elements referred to, few diseases require a larger number of cases to furnish reliable therapeutic data, so that statistics, to be really trustworthy must be based upon thousands, rather than hundreds, of cases, all subjected to the same treatment, under approximately similar conditions. Dr. Butler did not wish to be considered as advocating therapeutic nihilism; on the contrary, he believed it criminal to allow a grave case of pneumonia to sink to a fatal termination without the use of remedies and measures which have, so far as human judgment can determine, more than once turned the scale in favor of life.

Routine Measures and Precautions.—In considering the therapeutic management it is convenient to consider first the mild and uncomplicated, second, the severe or complicated cases. It should not be forgotten also that by the development of grave symptoms a case of the first class may shift into the second. There are certain routine measures and precautions which are required in every case, whether mild or severe. The room should be especially well-ventilated in order that the laboring lungs may receive air containing the maximum percentage of oxygen. Nothing is gained by the overload of bed-clothing so commonly seen, and personally he has long since discarded the pneumonia jacket in this form of the disease, unless when especially requested. The objections are that too much bedclothing or swathing the trunk in cotton tends both to keep the fever at a somewhat higher point than would otherwise be the case, and also adds materially to the discomfort of the patient. It is desirable that the body clothing, which should be of medium thickness, should be so arranged (by splitting part way up the back, if necessary) as to permit physical examination with a minimum of disturbance to the patient. Undue physical diagnostic zeal is to be avoided. Other points of importance are: Absolute rest in the recumbent position, with the use of the bed pan and urinal, and the free and regular giving of water, plain or mineral, both for eliminating toxins and keeping the renal tubules flushed out. For the latter purpose 8 to 16 ounces of normal saline solution by the rectum is also often of service. The diet should be that usually given in fever. In speaking on this point he said that one or two ounces of lactose daily, tasteless and easily soluble in most fluids, is a really helpful food, and may furnish many needed calories. Medicinally, at the onset of every case a small dose of calomel is of benefit; also a dose of 7 or 8 grains of quinine, given preferably by hypodermic injection, and repeated the following day.

Creosote Carbonate.—Creosote carbonate is a remedy in which he feels a certain amount of confidence. While he could not say that in any case the duration of the disease was shortened, under the use of this drug it tended to run a milder course, the temperature-curve, instead of remaining persistently high, dropped a little from day to day until at the time of crisis it had but a comparatively slight distance to fall to the normal or below. Also, there was apt to be a distinct diminution in the intensity of the toxemic symptoms, less delirium, less tremor, less cardiac weakness, and less meteorism. While it is impossible to believe that creosote acts as a germicide in the blood and tissues, he said, these results (noted in about forty cases), if confirmed by sufficient additional observation, are suggestive of a possible autotoxic action of the remedy.

To Relieve Pain and Cough.—Pain should be relieved preferably by a mustard draft, poulticing, or the ice-bag; using also, if necessary, morphine hypodermatically or Dover's powder by the mouth, in the smallest doses that will accomplish the desired purpose. In rare instances a tight chest bandage is efficacious. For irritating cough, steam inhalations of menthol and benzoin may be employed. Narcotics are to be avoided, if possible, but morphine and Dover's powder are often necessary. The treatment just outlined is all that is required for mild cases.

The Treatment of Severe Cases.—Delirium, restlessness and persistent insomnia may require one or more of the following: trional, bromides, Dover's powder in small doses, chloral (10 grains) cautiously, cam-

phor, hyoscine hydrobromate ($^1/_{100}$ gr.), with morphine ($^1/_8$ gr.) hypodermically, and the ice-bag to the head. Hyperpyrexia. Unless the temperature is continuously at or above 105° F. it is probably not worth while to attempt to lower it. The hypodermatic use of quinine is helpful; also the ice-bag to head and chest. The employment of the cold tub is unjustifiable, except occasionally in children, but the cold mitten rub has given excellent results not only in reducing temperature, but also because of its tonic action upon the nervous system. This may be repeated at intervals of from three to six hours when the temperature remains persistently at 105° F. or higher. In the first rub the water employed may be at 85° F., the second at 80° F., the third at 75° F.; subsequently not below 65°. Tympanites, which is an extremely undesirable occurrence because of its mechanical interference with the action of the diaphragm and heart, is probably less liable to occur when creosote carbonate is regularly given. When it appears, the following measures may be employed: Cutting down the nourishment (not the water) one-half, or suspending it altogether for twenty-four hours; a moderate dose of calomel and soda; enemata, plain, or containing turpentine, musk, or milk of asafetida; the use of the rectal tube. To stimulate the muscular coat of the bowel the following are useful: momentary intermittent rubbing of the abdomen with an ice-water cloth; 20 grains of quinine bisulphate and one-fiftieth grain of atropine by enema, or half these doses hypodermatically; $^1/_{120}$ of a grain of eserine sulphate by the mouth every four to six hours. The latter is especially recommended.

Oxygen.—Cyanosis, when arising from restriction of the respiratory movements in consequence of pain, is lessened by relief of the latter; when due to cardiac weakness or pulmonary edema it requires treatment of the special cause. Dr. Butler is a believer in the use of oxygen, in spite of the many contrary criticisms, because he has found in a majority of cases that when properly given it lessens cyanosis, slows the respiration, and affords a distinct sensation of well-being to the patient. The ordinary inhaling mouth-piece should invariably be replaced by a glass funnel of three or four inches diameter, and the latter should be held, an inch or so away, over the nose and mouth. Small doses of oxygen at frequent intervals are best. It is well to direct the nurse to allow the bubbles of gas to come about at the rate of 150 per minute, thereby avoiding useless waste of a somewhat expensive commodity.

Cardiac Weakness.—Cardiac weakness is perhaps the main source of danger in pneumonia. Circulatory impairment in the early stage of the disease is in all probability due for the most part to the depressing effect of the toxemia on the central vasomotor apparatus; in the later stages and during convalescence, to acute myocardial disease. Strychnine, the muscle energizer and central vasomotor stimulant, is a remedy of the first value. One-fortieth or one-twentieth grain, or even more, should be given every two hours, and it should be administered hypodermatically if prompt action is desired, or if there is the least doubt as to its absorption by the stomach. Next to strychnine is caffeine, either in the form of the citrate, or, better, as strong black coffee—one to two ounces every two to four hours. Brandy, whisky, the stronger wines, camphor, and aromatic spirit of ammonia are useful adjuvants; digitalis, nitroglycerin, strophanthus and sparteine may be given in full doses. An occasional dose of atropine and quinine bisulphate hypodermatically is of service, and the rectal administration of strong coffee with whisky or an emulsion containing 30 grains of musk may be called for in urgent cases. The possible usefulness of the powdered suprarenal, or its active principle, should also be borne in mind. Swathing the thorax in flannel wrung out of hot mustard water is often advantageous. The use of morphine in small doses ($^1/_{50}$ to $^1/_{12}$ grain, repeated or increased according to circumstances) will accomplish results obtained by no other drug; quieting and soothing the patient and steadying and improving the action of the heart. Especially if constipation, flatulence, or edema be present, calomel and compound jalap powder, in full dose, may act very happily; or some saline may be substituted. The subcutaneous administration of a pint or two of normal salt solution is a resource not to be neglected in grave cases.

Pulmonary Edema.—This demands in particular repeated dry cupping, hot mustard fomentations, calomel and jalap, large doses of nitroglycerin, moderate doses of atropine, and the free use of oxygen. The judicious physician will constantly endeavor to carry through the individual case with watchful expectancy, the least possible of meddlesome therapeutics, and the careful conservation of the patient's strength. While, however, giving as little active treatment as the case will allow, he will not hesitate to employ the most active and vigorous treatment when it seems indicated, making use of every measure which clinical experience has proved to be of value, though even slight.

Creosote and Quinine not Beneficial.—Dr. A. A. Smith said he was thoroughly in accord with most of the views advanced in the paper. His experience with creosote, however, was of a character contrary to that of Dr. Butler. In his hands it had proved of no benefit whatever, with the exception of cases where the disease was confined to one lobe and there was a general bronchitis present. He had also found it useful, in small doses, in tympanites. Neither could he endorse the use of quinine, except it might be on account of the presence of occasional special conditions, and stated his conviction that in the large doses in which it was formerly given the depressing effect of this drug had sometimes led to fatal results. Like Dr. Butler, he advocated the use of oxygen, and said that he had often seen good results from it when there were cyanosis, pulmonary edema, etc. There appeared to him to be certain objections to the mitten rub. These were purely clinical, such as disturbance to the patient. For the application of either cold or heat he preferred the use of flannel wrung out of water and constituting a compress. To serve the best purpose it was necessary that it should be applied to a large surface of the body, and he believed that this measure was a valuable respiratory and circulatory stimulant, and, above all, a marked nervous sedative. Recently, he had obtained good results by keeping the flannels at a temperature of 90° F.

Cardiac Weakness.—Personally, he was a firm believer in the very pronounced influence of the nervous system in producing cardiac weakness, and he thought it was through this that we could best afford support to the heart. It was through the agency of the nervous system that strychnine was so beneficial. Alcohol was apt to be given too early and too freely. It should be administered in moderate quantities, and in the majority of instances was not required at all. It was of great value, however, in cases occurring in chronic alcoholics, and here it should be begun very early, as the active delirium apt to be met with in such cases has a most disastrous effect upon the nervous system. Nitroglycerin was a great aid to other remedies, such as strychnine and caffeine, and was absolutely safe.

Dr. George L. Peabody thought the treatment might be divided into (1) an intelligent symptomatic treatment, and (2) an attempt at a specific or definite treatment. As to the first, delirium seemed to him one of the most troublesome and grave symptoms, and in his

experience delirium with high fever could not be well treated by means of drugs. These were greatly inferior to hydrotherapy, and although Dr. Butler considered it unjustifiable to put a pneumonia patient in the tub, he believed that he had convinced several generations of hospital internes that the cold bath, precisely as used in typhoid fever, was the best treatment for raving alcoholics with high temperature. If this method seemed too heroic (the patient being very feeble), or if there were delirium without sufficient fever to justify the cold bath, he was accustomed to use the cold pack, for which he thought linen greatly superior to woolen or cotton. In speaking of specific treatment he said that he quite agreed with Dr. Butler as to the necessity of a very large number of cases in order to arrive at any definite conclusions. He would only give his experience with a limited number for what it was worth. He had been favorably impressed with the salicylates. Aspirin was an excellent way of giving salicylic acid. Under its use patients appeared to stand the disease better than otherwise. Crisis was uncommon; lysis the rule. During February, March and April, 1903, he treated 43 cases with creosote carbonate. In these lysis was noted in 48 per cent., and crisis in 21 per cent. Thirteen patients, or 30 per cent., died. He was not yet convinced that we have any specific for pneumonia. At present he considered it the best plan to employ an intelligent symptomatic treatment, in addition to the administration of one of the so-called specifics.

Venesection.—Dr. Herbert F. Williams said there was one measure which, when properly used, outweighs everything else in importance. By venesection the overburdened heart is relieved, the blood robbed of an appreciable quantity of exudation product, and the pneumonic process thereby limited. It is most apt to be called for in the robust and well-to-do, whose fund of health seems contributory to the intensity of their pneumonia. The statistics of our fathers in the treatment of such cases, he thought, would not suffer in comparison with those of their sons. In lesser pneumonias, even lobar, pain is often an early and obstinate symptom, and can be relieved better by other means than opiates. The seat of the pain is in the pleuræ, and by a unique anatomical and physiological association of the cutaneous intercostal and visceral nerves we can influence the circulatory condition in the pleuræ by directing the current towards the surface. This is the *rationale* of the law of counter-irritation, and, as applied to pneumonia, it cannot be better secured than by wet cupping directly over the inflamed point. The contingent effect of the immediate relief from pain thus afforded may be more radical upon the pneumonic process than one would lightly suppose; for the relief of pain permits a full inspiration. He had often seen a bronchial respiration thus reduced to bronchovesicular, and believed that wet cupping was not only a safe, but a mandatory, procedure in early pneumonia.

The Failure of the Right Heart.—Dr. C. F. Wainright said that as it was the right heart which failed, the pulse did not afford an adequate indication of the true condition, and dwelt upon the cardiac results of sepsis. There was an effort made at compensation, and the evidence of the condition of the heart (with stagnation of blood in the right ventricle) was seen in dyspnea, edema of the healthy lung, and prune juice sputum. Calomel was of great service in unloading the portal circulation, and was also one of the best remedies to dilate the peripheral vessels. Nitroglycerin or sodium nitrate might also be employed for this purpose. If the heart had not been previously enfeebled, digitalis and strophanthus were called for.

The Prevention of Pneumonia.—Dr. H. W. Berg said that the disease could be prevented. It was now pretty well established that pneumonia is an infectious disease; we could even go a little further and call it a contagious disease. He had known of instances in which two or three cases occurred in the same family, and in his service at the Willard Parker Hospital it was his practice to separate the diphtheria patients who had pneumonia from the others. He thought that in pneumonia the same precautions should be taken as regards sputa, bed-clothes, etc., as in pulmonary tuberculosis; also that the healthy members of the family should not be subjected to the risk of contracting the disease.

Differences Between Pneumonia in Adults and in Children.—Another point to which he desired to call attention was the great difference between the pneumonias of children and of adults. Bronchopneumonia was a very serious disease in children. Croupous pneumonia was much less serious in them, and in this form of the disease his recoveries had amounted to 98 per cent. The child heart was much less susceptible to the deleterious action of the pneumococcus than the adult heart. In children there was one method of treatment that was very efficacious—namely, the cold pack (not the wet), applied every half-hour, or even quarter-hour, if necessary. He did not dare employ this in adults, except sometimes for the purpose of relieving pleuritic pain. He believed that the use of morphine was injurious in pneumonia, drying up the secretions and diminishing the chances of recovery. He would consder it justifiable only when necessary to relieve pleuritic pain.

SOCIETY OF GERMAN PHYSICIANS.

Seventy-fifth Annual Meeting, held at Kassel, September 20-26, 1903.

Portals of Entry of Plague Infection.—Contrary to a good many physicians, Schottelius believes that the plague germ is rarely inhaled, but generally enters the system through some loss of continuity of the skin. The local lesions are frequently small, and may readily be overlooked. Occasionally the infection starts from small cracks in the mouth or isthmus of the fauces. The infection of the lung is secondary to implication of the deeper cervical glands. The white race is relatively immune, and only poorly nourished individuals are apt to become affected.

Treatment of Articular Rheumatism with Antistreptococcus Serum.—Subacute cases which have resisted other treatment are especially benefited by serum, which has not, however, any specific action, according to A. Schmidt. Fifteen to 20 c.c. are injected daily for eight days in the region of the joints. The more distinct the reaction, the more likely the patient will be benefited.

Chronic Interstitial Pneumonia.—Damsch describes a slow, chronic pneumonia, non-tuberculous in character which leads to increased rigidity of the lungs without contraction or the formation of bronchiectatic cavities. Fever is generally absent, and the chief danger lies in displacement or relative insufficiency of the heart.

Roentgen Rays in Carcinoma of the Breast.—A remarkable case is demonstrated by Kronfeld. The carcinoma had ulcerated and formed multiple metastases in the skin and axilla, so that operation was excluded. After the third treatment the severe lancinating pains diminished and the ulcer stopped secreting. Four months later the entire tumor was replaced by scar tis-

sue, and the patient's condition had improved remarkably.

Urethrism.—A spasm of the urethra, similar to vaginism, is described by Ziemssen. The treatment consists in slow dilatation with injection of water into the bladder.

Leucocyte Count in Appendicitis.—Rehn believes the practice of counting the white cells to determine the pathological condition of the appendix superfluous and even dangerous, since valuable time is lost. Even when the figures diminish rapidly, pus may be present in large quantities.

Rare Symptoms of Ectopic Testicle.—A boy thirteen years old gave all the typical signs of appendicitis and was treated for such. The following day, Wohlgemuth was surprised to find the patient completely recovered. The symptoms had been caused by an ectopic testicle which had forced its way through the inguinal canal.

Intussusception.—Braun believes that acute invagination is due to a spasm of the intussusceptum and not to a paralysis of the intussuscipiens. The diagnosis is generally easy; healthy children are suddenly seized with tenesmus, vomiting and bloody diarrhea and lose ground rapidly. The tumor can often be felt. Chronic invagination is recognized with difficulty. The only effective treatment is operation. Acute cases should be operated so early that desinvagination is possible; for chronic cases entero-anastomosis is to be preferred. Resection gives good results only in adults.

Kredel was unable to reduce the invagination and prefers resection, though all of his cases died. Nevertheless, operation is indicated, since spontaneous cure is extremely rare. Replacing the intestines is often very difficult, even if the dilated gut is incised. The very first day should be chosen for operation.

Treatment of Tuberculous Peritonitis.—In both exudative and adhesive tuberculosis of the peritoneum, laparotomy offers much better chances than puncture or expectant treatment, according to Thones. Only the latter is, however, indicated in florid phthisis.

Treatment of Purulent Peritonitis and of Fat Necrosis.—The danger of collapse in purulent peritonitis is best avoided by means of saline infusions; 3½ liters should be used at once and 20 liters on the following day. The results are also satisfactory in fat necrosis of the peritoneum.

Treatment of Congenital Dilatation of the Colon.—High enemata, puncture of the dilated intestines, enteroanastomosis, preternatural anus and resection have all been recommended for Hirschsprung's disease, but the value of each method has not been definitely settled, since the condition is very rare. Braun removed the sigmoid flexure in one case.

Tuberculosis and Pregnancy.—Tuberculosis is a very grave complication of pregnancy, and it is frequently advisable to induce abortion in order to save the mother. Though some patients do surprisingly well, a fatal hemorrhage may appear at any time. Veit recommends an accurate control of the body-weight. When the patient steadily gains, abortion is never permissible, when she loses, removal of the fetus will hardly check the morbid process. The important thing is to cure the tuberculosis before permitting the woman to become pregnant. Even where the parents are in advanced stages of phthisis, healthy children may be reared.

Contraindications to Marriage.—According to O. O. Fellner patients should not be allowed to marry if suffering from progressive pulmonary tuberculosis, laryngeal tuberculosis, mitral stenosis and other valvular lesions with loss of compensation, myocarditis, chronic nephritis and malignant tumors. In married women, subsequent pregnancies are contraindicated in severe chorea, mental disease, severe epilepsy, tuberculosis and Basedow's disease. Eclampsia does not interfere, since it rarely recurs.

Prevention of Tuberculosis.—The views of Behring are rather iconoclastic, for he believes that tuberculosis is always acquired by way of the alimentary canal. The infection always dates back to infancy, during which period the bacilli only too readily wander through the walls of the intestines. Bovine and human tuberculosis are therefore identical, and a curative agent obtained from the spleen of immunized animals is promised.

Relation of Functional Nervous Diseases to the Female Sexual Organs.—B. Krönig has frequently noticed that diseases of the sexual tract accompanied by severe hemorrhage and prolonged inflammation can set up neurasthenia in its typical form. Physiological function, such as labor, if rapidly repeated may also be responsible. Hysteria may have a similar causation. Sexual abstinence is of no importance in bringing about disease. Sexual abuse impairs the nervous system less frequently than in the male. The importance of slight lesions has often been overestimated; this is especially the case with lacerations of the perineum, movable retroflexed uterus and posterior parametritis. Certain symptoms, instead of being the cause, are merely part and parcel of the hysteria; this applies to dysmenorrhea and the vasomotor and trophic disturbances of the menopause. Neurasthenia and hysteria do not exclude local treatment; on the contrary, they may make this imperative, as in the case of fibroids with recurring hemorrhages which increase the severity of the symptoms. Conservative operations must not be regarded as severe psychical results when compared with those on other organs. In especially severe cases of neurasthenia abortion may be necessary, but castration is only justifiable if the woman is near the menopause.

Protection of the Fetus against Infectious Disease.—Most infectious diseases may pass from the mother to the fetus in utero, but the latter seems to have a high degree of immunity since the antitoxins pass through the placenta earlier than the toxins. W. Hahn points out that the powers of resistence vary considerably; in tuberculosis they are very high.

Treatment of Chronic Gonorrhea.—The reason why urethritis is so difficult to cure in women is because the follicles and ducts are generally infected. E. Falk, therefore, splits them and treats all the recesses with the Pacquelin. In the uterus, weak solutions of protargol or lysol are excellent. If exudates are found in the tubes an abdominal operation should be performed only if a general peritonitis has developed, or if a neighboring organ has been perforated. In other cases, the vaginal radical operation is performed, but where the tube lies close to the vagina it may be simply incised and irrigated.

Etiology of Kraurosis Vulvæ.—Jung looks upon kraurosis vulvæ as the end stage of a chronic inflammatory process which may be set up by gonorrhea, pruritis, tuberculosis or carcinoma.

Salivary Glands in Infants.—Contrary to most observers, Schilling could demonstrate the presence of an amylolytic ferment in infants nine days to six months old. The parotid and pancreas are also active at this age.

Peptonized Milk in Intestinal Disturbances.—Diluted, peptonized milk tried by Reinach in chronic intestinal derangements of children, did not prove a success, but acute disturbances were favorably influenced. Microscopical examination of the feces is an invaluable aid in determining how a certain preparation agrees with the child and the food should be so modified that neither fat, carbohydrate nor proteid appears in excess in the stool.

Enterocatarrh of Infancy.—Salge isolated the blue bacillus previously described by Escherich from the stools of a number of cases of severe acute enteritis with toxic symptoms. All attempts to demonstrate pathogenic properties by growing on different media and by animal experiments failed, however. The toxicity in the human body probably depends upon the production of acids.

Trophodermatoneurosis.—A new disease, noticed in female children between one and a half and three years is described by Selter. It manifests itself in marked psychical disturbances with profuse perspiration, sudamina and red swelling of hands and feet. The duration is three to four months, the prognosis favorable.

Size of Thymus Gland.—The thymus gland throws a distinct shadow upon X-ray plates, which, under normal conditions during infancy, is only slightly broader than that of the vertebral column. A hypertrophied gland was found by Hochsinger in 20 cases of congenital stridor, that is, a type of respiration, especially loud at the end of inspiration. A large thymus was also found in 23 of 32 cases of rachitis.

Laryngitis Aphthosa.—Aphthous stomatitis is generally harmless, but Zuppinger has seen several cases where it extended into the alimentary tract and larynx. In the latter location there may be decided danger of suffocation. The treatment calls for the energetic use of permanganate of potash locally, inhalation of steam and warm compresses to the neck.

Treatment of Constipation by Hypnotism.—By means of hypnotic suggestion the sluggish innervation of the intestines may be increased where all other measures have failed. Delius has not only relieved the immediate condition, but has accomplished permanent cures. Equally good results were obtained in functional diarrheas.

A New Carbonated Bath.—Fisch recommends his carbonated baths in which the carbonic acid can be accurately dosed so that a gradual increase is possible. They are indicated in chlorosis, anemia, circulatory disturbances and during convalescence.

Etiology of Fever.—Klemperer has conducted some experiments which prove that rise of temperature is not caused by albumoses set free by the disintegration of body-cells. Albumose obtained from yeast and freed from bacteria, never sets up fever when injected into animals. When allowed to stand until all the proteid is destroyed, small amounts are already active, which is probably due to tyrosin formed.

Portal of Entry of Tuberculosis.—In almost a thousand autopsies on children who had suffered from some infectious disease, only five cases were found here tuberculosis involved only the intestines and mesenteric glands. Almost 25 per cent. had tuberculosis elsewhere. Ganghofner uses these figures as argument that bovine tuberculosis plays only an insubordinate role in the etiology of human tuberculosis.

Surgical Treatment of Chronic Nephritis.—Both incision of the capsule and decapsulation are occasionally justifiable in chronic nephritis as they may be the only means we have of prolonging life. Rehn suggests great care in the selection of cases as the operation may hasten the end.

Regeneration of the Ligated Saphenous Vein.—Ledderhose has convinced himself repeatedly that tying the saphenous vein does not always cure varicosities of the leg. In cases that were operated a second time he noticed a complete regeneration of the excised portion.

Sterilization of Catgut.—v. Hippel finds that catgut preserved in an aqueous iodine-iodide of potash solution will be sterile in one and a half hours. The iodine absorbed by the catgut will exert an antiseptic action upon the wound. Absorption is not delayed and the strength of the ligature is not impaired.

Relation Between Diphtheria and Scarlet Fever.—Uffenheimer's investigations were inspired by the difference of opinion which still exists as to the frequency of true diphtheria in scarlet fever. In 182 cases of the latter disease there were 127 with membranes and of these, bacilli were found in 30 per cent. In 11 per cent. there was a primary diphtheria, in 16 per cent. scarlet fever and diphtheria appeared at the same time and in 3 per cent. the diphtheria appeared later. The first class gave the worst prognosis. Sometimes Loeffler bacilli were found with only slight follicular inflammation, while in the most extensive membranes they were occasionally absent. Compared with former years, scarlet fever with throat affection has increased, but the specific germ was found less often.

Ehrlich's New Reaction.—Neubauer has discovered that the red color which forms if urine is treated with a solution of dimethylaminobenzolaldehyde in hydrochloric acid is due to urobilinogen. The reaction is especially marked in pneumonia and some blood and liver diseases. Absence of reaction in icteric urine points to complete occlusion of the choledochus or hepaticus. Bile and feces will also react since both contain urobilinogen.

Alkaptonuria.—This peculiar condition is now considered to be a manifestation of faulty metabolism. Falta believes that in normal individuals the tyrosin molecule of albumin is also converted into homagentisic acid and then further decomposed. In alkaptonuria the process is not, however, carried so far so that this acid appears in the urine.

Salt and Fluids in Heart and Renal Disease.—From purely theoretical premises, Strauss thinks it more advisable to diminish the sodium chloride in renal dropsies, while in cardiac dropsy, restriction of fluid is more important.

New Method of Measuring Temperature.—Weintraub obtains a continuous record of temperature by means of small elements introduced into the rectum and connected by long wires with a galvanometer. Variations as small as one-twentieth degree could be indicated.

Action of Salts in Baths.—Formerly it was believed that salts pass through the skin and enter the blood stream, but Frankenhäuser claims that their action is purely physical. In a saline bath, patients are surrounded by a medium which diminishes the dispersion of warmth and the loss of water from the skin, and which thus favors a better cutaneous circulation.

X-rays to Determine the Size of the Heart.—The only correct way we have to determine the size of the heart is by transillumination. The X-rays fail to show an increase in size with different positions of the body, after exercise, baths or the ingestion of alcohol. In aortic insufficiency a much larger shadow is obtained. This is not influenced by baths, but digitalis diminishes it considerably. In nervous hearts Grunach found three different shapes. (1) Normal shape; (2) duck-shape, owing to cardiaptosis; (3) enlargement, with trigeminal pulse.

Chemical Test for Leucocytosis.—When a blood count cannot be done, E. Mayer recommends the guaiac test, since this will be positive if more than 19,000 white cells are present. With a very large number, the addition of turpentine becomes unnecessary, since a ferment, which has the same action, is dissolved out of the cells.

Treatment of Adhesions.—A 10- to 20-per-cent. solution of thiosinamin in glycerin and water as injection is recommended by Friedlander. Marked improvement in general and local symptoms followed in all cases. He suggests also trying the remedy in peritoneal adhesions.

Cutaneous Tuberculide.—J. Comby advises changing the name of lichen scrophulosum into cutaneous tuberculide since it is really a manifestation of skin tuberculosis. Measles and pertussis favor its appearance by mobilizing bacilli, which have remained hidden in the body. The eruption is very easily cured, but it is important to recognize it, since it generally indicates a latent tuberculosis in some other organ.

Action of Phosphorus on Rachitis.—In none of the cases of rachitis examined could Stoelzner detect any pathological changes traceable to the action of the drug. Its efficiency is not, however, disproven since all three cases were of the severest type.

Hereditability of Rachitis.—F. Siegert believes that heredity is one of the most important etiological factors of rachitis. In most cases the mother has suffered from the disease in her youth. Even if such children receive natural food, they will not be protected from the disease. Prolonged nursing and advanced age of the mother play no part. An infection as cause is excluded. The social evil and diseases of the digestive and respiratory tract are the most important predisposing factors next to heredity.

The Rachitic Hand.—The delayed and incomplete development of the nuclei of the carpal bones and their epiphyses is considered by F. Siegert typical for the rachitic hand. The epiphyses of the ulna are first affected then those of the radium, distal ends of the metacarpals. The hand is generally long and narrow, while in myxedema it is short and broad.

Recent Operations for Prolapse.—Frank states there is no best operation for prolapse since the local conditions vary with every case. The most severe cases are generally easiest to treat, since they occur at an age where uterus and vagina no longer play an important part. The steps in an operation for total prolapse are the same as for a hernia: Reduction, removal of the sac (the invaginated peritoneum), and closure of the ring and canal. Sometimes it is best to simply remove the uterus with the greater part of the vagina and pelvic peritoneum. The uterus is here pulled downward, the vagina incised at the level of the fundus and the vessels of the parametrium ligated extraperitoneally. The peritoneum is not incised, but the entire prolapsed mass is simply tied off with an elastic ligature, and then cut off like a polyp. The remainder of the vagina is removed from below and the fasciæ and muscles are reunited in a second sitting. With marked cystocele or rectocele, the bladder or rectal wall must be invaginated by catgut ligatures.

Ventrofixture and Vaginifixture.—Many gynecologists believe these two operations are not indicated if the patient is still liable to bear children, but v. Guérard emphatically states that this is not so, if the fixation is not too firm. With only two or three ligatures beneath the fundus, dystocia is improbable. In 57 births after ventrofixture, a recurrence was noticed only twice. In 51 the subsequent labors were normal, in 5 the forceps were necessary, and in one case there was severe atony. In 41 cases after vaginifixture, the forceps were applied four times. Abortions were not noticed more often than with normal conditions.

Hot-air Treatment in Gynecology.—Hot air is much more efficient for chronic pelvic exudates than hot water. Tuszkai could find no change in the physical signs, but the pain and other symptoms rapidly disappear and the patients are again able to work. Probably the exudates are not absorbed, but become chronic more rapidly. The temperature should be gradually increased up the 80 to 90° C., which can be readily borne without burning the parts.

Pathology of Ectopic Gestation.—An interesting contribution to the pathology of extrauterine pregnancy is given by O. Fellner. He finds that in the majority of cases the ovum is imbedded in a diverticulum of the tube and not in the tube itself. The musculature of these diverticula is generally so poorly developed that the ovum cannot be expelled. Unlike the mucous lining of the tube proper, that of the diverticula is unable to form a true decidua, so that the imprisoned ovum rapidly dies. Where a decidua has formed the pouch was probably so shallow that the mucosa of the tube proper invested the egg.

Source of Puerperal Infection.—In every clinic cases of puerperal infection will occasionally occur, despite the most careful asepsis. If pains are taken, the origin can, however, be traced in most instances. Thus Buttner speaks of the possibility of a simple angina being at fault. He has experienced an epidemic with six deaths, where the infection probably traveled from a sore throat.

Double Pregnancy.—v. Neugebauer demonstrated specimens from a case of combined intra- and extrauterine gestation. The ova were of different ages, the normal one being ten weeks old and the ectopic one fourteen to seventeen days. Though the right tube was found ruptured, both corpora lutea were situated in the left ovary. In looking over the literature, 129 similar cases were encountered.

Treatment of Uncomplicated Retroflexion.—The disturbances following retroflexion are usually due to cervical catarrh, endometritis or diseased adnexa, according to Koetschau. In many flexions, the uterine changes are responsible for symptoms and change of position both. A parenchymatous metritis will remain, and will continue to cause suffering, even if the flexion is corrected. But uncomplicated cases may also give rise to symptoms, such as headache, gastric pain, backache and habitual abortion. Treatment is, therefore, always indicated, especially since prolapse may otherwise follow.

BOOK REVIEWS.

Clinical Examination of the Urine and Urinary Diagnosis. A Clinical Guide for the Use of Practitioners and Students of Medicine and Surgery. By J. Bergen Ogden, M.D., formerly Instructor in Chemistry, Harvard University Medical School, Boston; Assistant in Clinical Pathology, Boston City Hospital, etc. Second revised edition. W. B. Saunders & Co., New York, Philadelphia and London.

Dr. Ogden's book, in its second edition, promises to prove even more useful to the practitioner than it was originally. Those familiar with it will recognize that this means much, since it is without doubt one of the most complete practical diagnostic manuals at present before the profession. It is exceptionally full and detailed, and the brief summary of diseases of the kidney in connection with the examination of the urine and urinary diagnosis makes it a very handy manual for the study of nephritic affections, since it does away with the need of further consultation, except in very difficult cases. The illustrations, especially those in colors, are very well executed and cannot but prove extremely helpful.

Diseases of the Skin. An Outline of the Principles and Practice of Dermatology. By Malcolm Morris, Consulting Surgeon to the Skin Department of St. Mary's Hospital, London. New Edition. W. T. Keener & Co., Chicago.

Dr. Morris' valuable little manual on skin diseases, though issued in its original edition only in 1898, has been out of print for some time. The writer has been

too busy to give the volume the attention he deemed necessary in order to bring it up to date. There is probably no other book of the same size in English that contains anything like the amount of information, in a very practical way, that is given in this. The index is especially valuable and is an important feature in the 600-page manual, particularly as it is arranged with special attention to cross references as regards treatment. Dr. Morris has always been a popular writer on this subject and his second edition will surely add to his reputation.

A COMPOUND OF HUMAN ANATOMY. By SAMUEL O. L. POTTER, M.A., M.D., M.R.C.P. Lond., Formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco; Author of the "Handbook of Materia Medica, Pharmacy and Therapeutics," "Quizcompend of Materia Medica," "Index of Comparative Therapeutics," and "Speech and Its Defects." Seventh edition. Revised and enlarged. P. Blakiston's Son & Co., Philadelphia.

SINCE the publication of this work for the first time, twenty years ago, it has proven to be of so much help to a goodly percentage of students in nearly all the medical colleges of the country that it now, in its up-to-date condition, requires no introduction to the medical profession. Gray's Anatomy has been taken as a basis for the work, but the present edition has been entirely rewritten and Morris, Quain and other recognized authorities have been freely consulted in the preparation of it. Although clearness and conciseness are important and well-deserved characteristics of this volume, it cannot be rightfully urged that these qualities have been attained by the omission of the essential features of the subjects treated. It is well illustrated by tables, plates and diagrams, many of them appearing for the first time in this edition. The student cannot fail to appreciate the helpfulness of such a standard book, especially in his preparations for quiz and examinations.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, etc. By Leading Members of the Medical Profession Throughout the World. Edited by A. O. J. KELLY, A.M., M.D. With the Collaboration of Regular Correspondents in Montreal, London, Paris, Berlin, Vienna, Leipzig, Brussels and Carlsbad. Volume III. Thirteenth Series. J. B. Lippincott Company, Philadelphia.

THE present volume of the International Clinics is occupied in its first hundred pages with a symposium on diseases of the gall-bladder and gall-ducts. This subject is so up-to-date in its interest that it can scarcely fail to attract attention. Among the contributors to the symposium are Dr. Musser, of Philadelphia, who discusses the medical aspect of biliary disease; Dr. Rudolph, of London, Ontario, who discusses the symptoms and diagnosis; Dr. Charles Stockton, of Buffalo, who discusses the medical treatment; Dr. F. Parks Weber, of London, England, who presents biliary cirrhosis of the liver, complicated by cholelithiasis; Dr. Lejars of the Faculty of Medicine of Paris, who suggests the indications for surgical intervention, and Dr. John B. Deaver, of Philadelphia, who discusses the surgical and postoperative treatment. All of the papers are thoroughly clinical in character, containing many practical hints and without any waste of words.

A very timely clinical lesson in the present volume is that on the treatment of pneumonia, by Dr. David W. Finlay, Professor of Medicine in the University of Aberdeen. Among the contributions on the subject of General Medicine are articles on clinical types of pneumonia, with special reference to aberrant forms, by Dr. R. Murray Leslie of London, and sudden death due to respiratory disorder, by Dr. Thomas J. Mays, of Philadelphia.

THE PRINCIPLES AND PRACTICE OF HYDROTHERAPY. A Guide to the Application of Water in Disease, for Students and Practitioners of Medicine. By SIMON BARUCH, M.D., Professor of Hydrotherapeutics in the New York Post-Graduate School, etc. Second Edition, Revised and Enlarged. William Wood & Co., New York.

DR. BARUCH has done much to bring hydrotherapy into good repute here in America. The present treatise, now in its second edition, is the best evidence of the serious character and valuable influence of his work. It is to be hoped that his contributions to the literature of the subject will finally bring about what has been so long his dearest wish, the regular teaching of hydrotherapy in the medical schools. The present volume contains an epitome of the history of hydrotherapy, which shows very distinctly how the neglect of the subject, by regular practitioners, has constantly thrown it into the hands of quacks and charlatans, with consequent obscuration of the good in it, to the detriment of therapeutics generally. Certainly anyone who reads Dr. Baruch's book attentively will be convinced of the great possibilities for good that there are in exact hydrotherapeutics, applied according to proper indication. The book deserves a place on the shelves of every general practitioner of medicine.

SURGICAL ASEPSIS. Especially Adapted to Operations in the Home of the Patient. By HENRY B. PALMER, M.D., Consulting Surgeon to the Central Maine General Hospital, With Ninety Illustrations. F. A. Davis Co., Philadelphia.

THIS little volume contains in condensed form the conclusions which investigators on asepsis have reached and gives directions for their application in practice. It is designed primarily for those deprived of the hospital facilities afforded by larger cities, and should prove a reliable *vade mecum* to the man thrown upon his own resources in operating. Many ingenious adaptations of easily obtainable articles to eke out surgical emergencies are described and the author will no doubt earn many thanks from colleagues for whom he has made easier the difficult path of asepsis.

NERVOUS AND MENTAL DISEASES. By ARCHIBALD CHURCH, M.D., Professor of Nervous and Mental Diseases and Head of Neurological Department, Northwestern University Medical School; and FREDERICK PETERSON, M.D., President New York State Commissioner in Lunacy; Chief of Clinic, Department of Nervous Diseases, College of Physicians and Surgeons, New York. Fourth Edition, Thoroughly Revised and Enlarged. W. B. Saunders & Co., Philadelphia, New York and London.

IN four years this text-book of nervous and mental diseases has reached its fourth edition. This is of itself sufficient evidence of its general appreciation by students and practitioners. The present edition contains a number of valuable additions, among them paragraphs on intermittent limping, now known to be dependent upon a definite pathological lesion situated in the posterior root ganglia, and some paragraphs devoted to the form epilepsy associated with mild myoclonus, an affection that has in recent years attracted a good deal of attention under the name of the combination disease.

A very valuable feature of the present edition is a chapter by Dr. Adolph Mayer, the head of the pathological department of the New York State Hospital for

the Insane, in which he discusses the present status of insanity, according to the views of the best known European specialists. In recent years a great change has come over the method of writing text-books of mental diseases, and certain of the prominent German alienists have attempted a new classification of the insanities. The best known of these authorities, Kraepelin, Wernicke, Ziehen, and Mendel, have made various suggestions as to the rearrangement of nervous diseases in such a way as to make their recognition and study more assured. Few men are better fitted than Dr. Mayer to give such a review as this, and this chapter of the book is one of the most informing contributions to the literature of mental diseases in America that has been made in some time.

The Treatment of Certain Malignant Growths by Excision of the External Carotids. By Robert H. M. Dawbarn, M.D., Professor of Surgery and Surgical Anatomy in the New York Polyclinic Medical School and Hospital; Visiting Surgeon to the City Hospital, New York, etc. (The Samuel D. Gross Prize Essay.) F. A. Davis Co., Philadelphia.

This little book is an excellent testimonial to some good, original work of great value done by an American surgeon. There is no doubt of the wisdom of the trustees of the Gross Prize in conferring on Dr. Dawbarn's essay the distinction it so well deserves. The method of treatment of course must still be tried in a great many cases before its absolute worth to surgery can be decided. Even though it should prove eventually not an operation of choice, being replaced by some more successful method of treatment, there is no doubt that the work done on it will remain as a landmark in our knowledge of surgical operations upon arteries, and will be a source of valuable information of the blood supply of the face. In the meantime, for sarcomatous growths the treatment is surely hopeful. For cancer it furnishes relief from pain and lengthens life in comparative comfort. Nothing in recent years has done more, if as much, in the realm of these obstinate and so often hopeless affections.

Consumption a Curable and Preventable Disease. What a Layman Should Know About It. By Lawrence Flick, M.D., Medical Director of the Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis. David McKay, Philadelphia.

Physicians are often asked how can a layman obtain a practical knowledge of the present position of the medical profession with regard to consumption, its cure and prevention. The best answer is to recommend a copy of this book. For charity workers, for nurses, for those who have relatives suffering from tuberculosis, for settlement workers, and visitors to slums, as well as for patients who are themselves suffering from tuberculosis there is no easier way of securing all the knowledge they need than by a perusal of this little volume. It has no technicalities; there is no waste of words. Dr. Flick makes many striking points. He discusses such questions as "Is Consumption Inherited?" "How Tuberculosis Is Spread," "Consumption as a House Disease, and the Rôle of the Workshop, the Store, the Office and Hotels and Boardinghouses in the Spread of Tuberculosis." At the same time he gives very encouraging answers as to how to avoid consumption, how to prevent its spread, how it can be cured in an early stage. At the end there is the discussion of the problems: "Should a Consumptive Marry?" and "Should a Consumptive Suckle Her Child?" The book will surely make a place for itself in the present crusade against tuberculosis.

The Surgical Treatment of Gastric and Duodenal Ulcers. By B. G. A. Moynihan, M.S. (Lond.), F.R.C.S., Eng., Senior Assistant Surgeon, Leeds General Infirmary; Consulting Surgeon to the Skipton Hospital, and to the Mirfield Memorial Hospital, etc. Illustrated. W. B. Saunders & Co., New York, Philadelphia and London.

The attractive personality exhibited by the author on the occasion of his recent visit to this country adds interest to the work in question as well as his eminence in the field of surgery it discusses. It is an ideal presentation of the results of one man's own work and the conclusions he has reached, and for systematic classification, clear-cut directness of expression and logical thought leaves nothing to be desired. The work is divided into four parts devoted to Perforation of Gastric or Duodenal Ulcers, Hemorrhage, Chronic Ulcer and Hour-glass Stomach. Under the first heading the author calls attention to the ease with which intestinal contents can reach the right iliac fossa in cases of perforated duodenal ulcer, and thus simulate, both before and during operation, acute appendicitis. In all cases of perforation it should be remembered that double perforation occurs in 20 per cent., the second ulcer usually being on the posterior wall of the stomach, exactly opposite the first, and the entire surface of the organ should, therefore, be scrutinized. In all cases of hemorrhage from a chronic ulcer operation should be performed at the earliest possible moment. Search for the bleeding points or excision of the individual ulcers, which are often very numerous, is not necessary; gastro-enterostomy will prevent further hemorrhage and lead to rapid healing of the ulcers. Duodenal ulcer rarely exists without the coexistence of gastric ulcer. The author advances the theory that duodenal ulceration occurs only, or at least most easily, with excess of free hydrochloric acid, and he believes the sequence of events to be gastric ulcer, hyperchlorhydria, duodenal ulcer. In performing his gastro-enterostomies the author has given up the use of mechanical aids and uses a simple and rapid method by suture, which is clearly described and figured. The consideration of hour-glass stomach, which follows, is of equal value and the statistical tables which complete the volume are valuable additions to the mathematics of the subject. Enough has been said to indicate the importance of the book, which will prove of interest to both medical men and surgeons.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Diseases of the Eye. By Drs. H. F. Hansel and W. M. Sweet. 8vo, 532 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Compend of Gynecology. By Dr. W. H. Wells. Third edition, Demi 8vo, 293 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

A Manual of Bacteriology. By Dr. Herbert N. Williams. 8vo, 351 pages. Third edition. Illustrated. P. Blakiston's Son & Co., Philadelphia.

A Text-Book of Obstetrics. By Dr. J. C. Webster. 8vo, 767 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

The Clinical Pathology of the Blood. By Dr. Jas. Ewing. Second edition. 8vo, 495 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

Lessons on the Eye for the Use of Undergraduate Students. By Dr. Frank L. Henderson. 8vo, 205 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

ORIGINAL ARTICLES.

PERIPHERAL NEURITIS. A CLINICOTHERAPEUTIC RESUME.

BY WILLIAM BROADDUS PRITCHARD, M.D.,
OF NEW YORK;
ADJUNCT PROFESSOR OF NERVOUS AND MENTAL DISEASES, NEW YORK POLYCLINIC; CONSULTING NEUROLOGIST, S. R. SMITH INFIRMARY, STATEN ISLAND.

THIRTY years ago, neurology was a comparatively unexplored by-path in the Mammoth Cave of medical research. Within thirty years, such gigantic strides have been made in this field as to make the net results of today seem almost miraculous. Brilliant as have been the achievements in localization, in brain surgery and in neuro pathology, no chapter in all this history is more marvelous in the sum total of practical results than that devoted to the study of neuritis. Beginning with the researches of Duchenne there followed in quick succession the investigations, clinical and laboratory, of Dumesnil, Jolly, Pitres and Vaillard, Bury, Leyden, Bowlby, Ross, and a host of others, the net result of which is a definite conception, with a correlated working basis, which places the subject unquestionably within the field of positive medical activities. We enter this domain of medicine today with the same confidence and assurance which marks the portals of surgery, gynecology, dermatology or any other special subfield of medicine. Because of the tremendous dimensions of the unrestricted subject, I shall limit myself to a consideration of the strictly clinical and therapeutic aspects of peripheral neuritis alone, leaving out of consideration altogether, the very inviting and interesting and important subject of multiple neuritis and also all questions of pathology and morbid anatomy. We shall find quite enough material in this restricted field to occupy your attention to the limits of tolerant patience. I have selected as the basis of what I shall have to say, the carefully recorded histories of six patients, taken from my case books. These patients represent six different clinical types of peripheral neuritis. These selected cases it should be remembered are more or less typical. The atypical and the anomalous should not be forgotten. I have endeavored in this paper to adjust general experience to individual variations and exceptions, as far as possible, but have quite probably fallen short in a relative estimate of the importance of the personal equation in every case of nerve trouble. The harm is less if you remember the acknowledgement and the implied emphasis which such acknowledgement places upon the fact.

Neuritis of the Seventh (Facial) Nerve.—This form which is very common, is attended with more or less marked motor paralysis, and is much more familiarly known as Bell's palsy. Other synonyms are rheumatic facial paralysis and car-window paralysis, the latter term being especially significant as to a frequent etiological factor, exposure to direct cold. The nerve is quite superficial in part of its course anatomically and but poorly protected from either trauma or cold. The importance of this form of neuritis is esthetic or cosmetic, and somewhat a matter of sex, rather than vital. In cases which do not recover the facial deformity from atrophy and asymmetry is almost tragic, if the patient be a woman. With face twisted awry, drooping, dribbling mouth angle, staring lagophthalmus and wasted muscles, the feminine victim of this form of neuritis, if it prove vicious, is a martyr indeed, and not very charitable, either, in her criticisms of the doctor who treated her, especially if she finds that he has been incompetent or negligent.

The most important first consideration in facial paralysis is the question as to whether the lesion is central or peripheral. If central, the case is infinitely more serious. Fortunately a mistake here is rarely made and is practically never excusable. In the central (brain) cases, the upper branch is infrequently affected, and if at all, only transiently, as a rule, and slightly. It is very uncommon for a cerebral lesion to pick out the facial center alone, sparing all others. If central and of the right face, there is almost necessarily aphasia in some degree and usually, even in lesions quite limited of the central or subjacent white fibers, there is associated implication of the arm of the same side, or of the arm and leg. Lagophthalmus is rare in the central cases, and so also is atrophy, though this latter fact is of less immediate importance, as it does not develop in any case until after a varying interval and the differential diagnosis must be made at once. The mode of onset is quite different, the central cases developing with apoplectiform symptoms, or at least with some general manifestations of cerebral disturbance. In the peripheral cases the patient quite often first discovers the paralysis on looking into a mirror, or from an unexpected dribbling of fluids in attempting to drink, or from an inability to whistle. The triple distinction of supranuclear, nuclear and terminal facial palsy is less vitally important though scientifically desirable. There is rarely, if ever, any sensory disturbance, unless the fifth nerve is simultaneously affected. This association paralysis of fifth and seventh is comparatively rare, although I have seen perhaps half a dozen examples.[1] It is quite often due to syphilis, which is very rarely a cause of Bell's palsy and is easily recognized by the additional symptoms of hyperalgesia and hyper-

[1] Read before the Richmond County (N. Y.) Medical Society, Nov. 11, 1903.

esthesia, followed by analgesia and anesthesia and by active and early trophic symptoms, particularly neurotrophic ophthalmia.

It is sometimes of importance to determine at what point the lesion in Bell's palsy exists and there are various signs, dependent upon the implication of certain branches, by which the anatomical extent of the disease can be determined. The prognosis, and to some extent, the conjectural etiology is dependent upon such determination. Practically it is sufficient to say in this connection, as regards prognosis, that if the analysis of symptoms points to a lesion outside of the stylo mastoid foramen, the prognosis is much better than if the lesion is within.

Case I.—A. B., aged thirty-six years, female, housewife, thin and anemic, family and personal history negative. Three weeks ago took an afternoon nap exposed to the draught of an open window. On waking noted a sensation of peculiar awkwardness and stiffness of left side of face, and on taking a look at herself in the mirror, found her face twisted awry, the left angle of the mouth drooping, with inability to close down the left eyelid (lagophthalmus). Three days later she reported at my clinic, and the following facts were noted. Motor paralysis, left side of face, all branches, no action of left corrugator supercilii, droop at left angle of mouth, some impairment of sensation of left side of tongue anteriorly (chorda tympani), hyperacusis left ear and no action of muscles of palatine arch, left side, on forced vocal expiration (requiring patient to say "Ah"). There is no disturbance of skin sensation, of the action of the ex- or intrinsic muscles of the eye and no implication of the arm or leg of the same or of the opposite side. The diagnosis is that of Bell's palsy, lesion within stylomastoid foramen, probably as high as the geniculate with a prognosis of recovery after two to four months active treatment. Considerable progress toward recovery has already occurred and she will ultimately and in all probability within the time limit already designated, make a good recovery, under the following plan of treatment: The face is massaged daily with inunctions of lanolin; the patient takes three doses daily of strychnine gr. $^1/_{25}$, quin. sulph. gr. 1, and sodii salicyl. gr. III, to which is added 5 gr. doses of Bland's mass and three times a week she is treated with galvanism. An Erb neck electrode 2 by 4 is applied back of the neck and to her left face is applied a flexible, adjustable Erb electrode, 2 by 4. Five to seven milliampères are introduced through the rheostat, and the seance lasts from ten to twenty minutes. Daily seances would hasten the result, and in obstinate cases, alternate seances with the interrupted current roller electrode or faradism, with a current of high tension, will prove advantageous, especially in controlling atrophy. It is at times of distinct advantage to use in these cases small doses (5 grs. t.i.d.) of potassium iodide. It seems scarcely necessary to add finally that in this patient's case all local etiological factors, such as aural or dental, or nasal disease, affections of the antrum and other similar conditions which would, if present, materially affect the treatment, have been excluded. An obvious etiology in any such local cause, invariably demands, of course, appropriate treatment.

Neuritis of the Sciatic Nerve, Sciatica.—The history of this case is as follows: In March, 1893, an attack of grip with severe throat and bronchial symptoms,[2] was followed immediately upon the subsidence of febrile symptoms by a sensation of tired, aching pain and quick fatigue in the right leg, the pain following the course of the sciatic nerve. A trip South relieved all symptoms except those involving disability and pain in the right leg. This leg became easily and quickly tired from any exertion and constant aching pain, plus a variety of abnormal sensations, numbness, tingling "pins and needles" and other paresthesia, developed. At home, at the theater, in church, anywhere, where the position was constrained, he felt this pain and these paresthesiæ. In May he presented the following symptoms: Pain, intensified by pressure, along the course of the sciatic nerve of the right leg, especially at the popliteal space and at the outer aspect of the ankle; slightly diminished power and some anesthesia in the area of cutaneous distribution; beginning atrophy as indicated by contrast measurements of the two legs which showed right middle thigh 17½, left 18½; right calf, 15¾, left 15¾; right ankle, 7⅛, left 7⅜. Bearing in mind the normal reversal of these measurements as between right and left, the continuous pain in an anatomically limited area, the paresthesiæ and other subjective symptoms, as well as the etiological history there was no hesitation in arriving at the diagnosis of sciatic neuritis, from infection. The following plan of treatment was at once inaugurated: Functional rest, as far as possible, the internal administration of quin. sulph. gr. 1, strychnine sulph. gr. $^1/_{40}$, and arsenious acid gr. $^1/_{50}$, t.i.d., with electricity in the form of galvanism, 5 to 10 milliampères daily, through the largest size Erb electrodes, one under the right foot, the patient sitting upon the other, the buttock being protected by a thick covering for the electrode. Daily massage, with lanolin as the emolient, was employed, very gently at first, all Swedish movements being avoided. Special importance was attached in the technique of electrical treatment, first, to a position of bodily comfort and non-restraint during the seance; second to a diffusion of the current by means of large electrodes; and third to an avoidance of shock or irritation effect by the invariable use of the rheostat. The meter should always be the guide as to quantity. This patient has practically made a complete recovery though still able on damp humid days, or after unusual fatigue, to tell the right leg from the left. Such a result, while by no means exceptional, is equally by no means the fixed rule. Sciatica is quite often a most obstinate affection and much more radical measures are often imperatively necessary.[3] The patient must be put to bed and

even more radical measures employed to enforce total physiological and functional rest. The long hip splint may be advisable. When applied, it should be adjusted so as to permit of the application of hot or cold (ice) bags along the course of the nerve or of actual cautery, a measure which is almost magically effective at times, especially if used early. With the patient in bed, the limb in a splint and a chain of ice or hot water bags as a cushion for the affected leg, acute suffering is often kept under control without more direct medication. Should drugs be necessary, as they often are in severe cases, do not waste much time with coal-tar analgesics or other compromise measures, but use morphine at once, hypodermically and in effective doses. It is infinitely more certain than the cocaine or osmic acid or water injections or needle punctures, variously recommended by Corning, Solis-Cohen, Bartholow, Starr, and others, and there is the further advantage that morphine need not be injected locally, whereas the other agents mentioned are dependent for effect upon a local and direct action, a procedure not without danger, as shown by the experiments of Pitres and Vaillard who have reported several cases of acute traumatic parenchymatous neuritis, the result of the employment of these methods. Phenacetin, antipyrin and other kindred drugs are sometimes transiently ameliorative, but disappointing in permanent effect. The salicylates, colchicum and the iodides are equally disappointing even when an associated rheumatic diathesis is evident. The sulphur pack, the castor oil plan and other empirical methods are always experimentally legitimate, especially in obstinate intractable cases, when the question of surgical interference by means of nerve stretching, section or other operative procedure forces itself upon your attention. In this connection, let me urge upon you, as a result of personal experience and a somewhat critical observation, the most extreme conservatism. Among other experiences, invariably disappointing and disastrous, I cannot easily forget a suit for damages which I once narrowly escaped. I had advised nerve stretching, as a last resort, in a most intractable sciatic neuritis. A very competent surgeon stretched the nerve by the open (operative) method, with the result that a painful disability became an absolute paralysis, and for many months the patient was dependent upon crutches for locomotion, the pain being no less, the last state of that man being infinitely worse than the first. Stretching the nerve by forcible flexion of the thigh upon the abdomen is less dangerous, but quite painful, requiring an anesthetic. Do not forget in all cases to examine the urine for diabetic or gouty states or lead, the blood for malaria and other parasites, the pelvis for tumors, uterine disease or other sources of intrapelvic pressure, the bones for hyperplastic inflammatory disease, the local blood-vessels for aneurisms or varicose dilations, any of which conditions may cause or aggravate a sciatica. Reflex irritation is infrequent, but one of the most severe and intractable lumbosacral neuralgias I ever saw was due to an undescended constricted testicle. Flatfoot may induce symptoms closely simulating sciatic neuritis, and I have known appropriate orthopedic treatment, or a change in the style or make of a shoe, to effect a cure quite promptly. In considering surgical measures, it is always well to bear in mind the vis medicatrix naturæ. A waiting policy quite often pays better than aggressive surgical interference.

Intercostal Neuritis.—Male, aged fifty-four years, of French ancestry and a most restless, nervous temperament. Thin, sallow, cadaveric almost in malnutrition, he tells a tale of marvelous endurance in various experiences. You know the type, the man "lives on his nerve." Now and then such men break down, usually mentally, sometimes motorially, less often sensorially. In this case, as in all therapeutic neurology, the equation of temperament, the nervous personal equation, is tremendously important, though often overlooked and quite as often misinterpreted. This patient tells me he has suffered from two previous attacks of neuritis, both involving the brachial plexus, one attack eleven years ago, the second five years later. I find from urinary analysis an intensely lithemic state. The specific gravity is 1.032, no sugar, but urea in extraordinary excess, 16 grs. to the ounce. There is also an excess of indican and microscopically, crystals of uric acid are abundant. Renal cells, traces of albumin, a few leucocytes and a few blood cells, with much mucus, are present as evidences of the mechanical irritant effect of these deposits. We know from pathological findings, that similar mechanical deposits within the nerve sheaths are not infrequently responsible for inflammatory interstitial affections of the intercostal and other nerves, an hypothesis which has always appealed to me. This patient's present attack developed three weeks ago. He was out fishing, got wet and wore his wet clothing for several hours. The following morning, he awoke with a stinging, burning pain in the right side, at the level of the sixth rib. The sensation was that of a red hot wire running under the skin from the middle of the back to the median line in front. Within twenty-four hours an eruption developed, linear in distribution and vesicular in character, corresponding to the line of pain. It looked like a line of angry blisters. The local physician, who was called in, made the diagnosis of "shingles" correctly, but failed to recognize the neurotic basis, and treated the case from a strictly dermatological standpoint. Salves, ointments and washes failed of relief, and the sufferings of the patient grew more intense. I was called in consultation at this stage. Aggravated insomnia, loss of appetite and extreme emotional instability and irritability had been added to the picture secondarily. Absolute rest in bed, gentle massage, forced feeding and galvanism were ordered and the following prescription was directed to be given every four hours: Sodii salicyl. gr. III, quin. sulph. gr. I, codeine gr. ¼. A lining of lamb's

wool fleece, which is rich in lanolin, was ordered to be basted as a skin side lining to the undershirt, over the affected area. A hypnotic powder of ten grains each of trional, sulphonal and sodii br. was ordered given in hot milk at bedtime. All symptoms, forty-eight hours later, were found to be worse. The nervous irritability, which was most intense and general, made the wool fleece intolerable, an uncontrollable motor restlessness rendered the rest plan impossible and the hypnotic had not only failed as an hypnotic, but had been followed by a collapse depression which was almost alarming. Electricity and massage had both apparently aggravated the neuritic pain. I changed tactics at once, abandoned the wool fleece, discontinued the electricity and both prescriptions, ordered champagne every two hours, and a prescription containing caffeine gr. ½, strychnine sulph. gr. 1/25, quin. sulph. gr. 1.½ in capsules, one every three hours, modified rest, forced feeding to be pushed more actively, and the massage continued. The effect was almost magical. The patient began almost immediately to improve and within a day or two, was sleeping well, eating well and practically free from all pain. Although still annoyed by various hyperesthesia as well as hyperalgesiæ in the area of the affected intercostal, he has since made a complete recovery. Unless employed at the very beginning, local measures such as blisters, poultices, ice, thermocautery, leeches, menthol and other sprays and anodyne salves and ointments are worse than useless. Promptly employed, some of them sometimes may arrest further progress, practically aborting the attack. If not effective within forty-eight hours, further continuance is at least negatively harmful.

I have never found any advantage from applications of galvanism through the bare metal electrode recommended by some authors. Indeed, this method is much more often positively harmful. Strapping the chest is at times beneficial, but not often necessary, and always very uncomfortable. The selection of the left rather than the right side is rather remarkable in these cases, and of some importance, especially in aged patients, in that in such cases it is quite imperative that angina pectoris in any form shall be excluded. Simulated mastodynia in women is often, if not always, a variety of intercostal neuralgia or neuritis. Pleurodynia is usually easily differentiated.

Neuritis of the Fifth Nerve, Trigeminal Neuritis, Tic douloureux.—Patient No. 4 is the victim of one of the most virulent and at times intractable forms of neuritis, known as tic douloureux. Painful spasmodic disease of the trigeminus is a competent definition. Although taxing your resources at times to the utmost, it is at the same time often a most fascinating prognostic and therapeutic problem. The etiology is exceedingly varied; sometimes it is due to trauma, again to cold, sometimes to infection as from erysipelas, aural disease or abscess. In other cases the cause is constitutional and the disease becomes one of the numerous nervous manifestations of the uric acid diathesis, of malaria, of gout or of diabetes; exogenous intoxication as from lead, alcohol, opium and arsenic may be the causative factor in special cases. Arterial degenerative disease such as atheroma or fibrosis with associated nutritional disturbances is a very common cause explaining the extraordinary frequency with which the disease occurs in the aged. Why females should preponderate numerically is not so easy of explanation, though none the less a fact. Perhaps the factor of broad diminished neurological resistance is a sufficient explanation. I find in examining my records that excluding traumatic cases, the females as compared with males are as three to one. I find also from the same records that 60 per cent. of my patients were past the age of fifty years. Quite often in these patients there is disease of the kidneys with resultant insufficient sewerage and non-elimination of toxins, and it is sometimes difficult to determine the exact etiological and allied therapeutic significance of the urinary findings. The urine should always and frequently be examined in all cases of tic douloureux, especially in the aged, and the findings should to some degree, at least, influence the treatment and prognosis. Blood analyses, especially for infectious or parasitic invasion should constitute a part of the routine study of these cases. Local conditions, such as carious teeth, alveolar disease, disease of the antrum, exostoses, malignant growths, suppurative disease of the ear or of the frontal sinus, of the nasal cavities or of the orbit are occasionally found to be causatively related directly or indirectly to this affection. Just here let me refer with emphasis to a fact of great importance in its bearing upon both prognosis and treatment in this and other sensory neuroses, and indeed in all the neuroses, motor and trophic, as well as sensory. Incidentally I might add that to an even greater degree in importance as a fact does it apply to the psychoses: *nerve function especially when perverted is peculiarly prone to habit tendencies. Starting in some local, definite cause or in some equally positive constitutional state, a neurosis, motor, sensory or visceral, motor, quickly develops a habit tendency which results in a continuation of the neurosis after the cause shall have ceased to act or shall have been removed surgically or otherwise.* Examples are both numerous and familiar in every day general experience. A fifth nerve neuralgia may begin from a carious tooth. Let the tooth remain for a few days, then extract it; the neuralgia should disappear at once upon the removal of the cause. Sometimes it does; quite as often it does not. The result, the effect, has to be treated as an entity, independently of the cause. Epilepsy, especially the traumatic variety, affords another example in point. Let a given epilepsy be due to direct local irritation at a certain circumscribed point by a definite lesion such as tumor, spicule of bone or clot. Let such local cause remain for a few weeks or months, then remove it with the

utmost nicety of surgical skill and precision. The positive cause having been removed, the resultant effect—epileptic attacks—should cease, but do they? In my experience, a large one, the epileptic attacks continue as often and as severely as before in a large majority of cases, and quite often the original condition is intensified. The same reasoning and experience and facts apply with equal importance to the tics. I have seen spasmodic torticollis originating in a local condition continue after such causative condition had been removed by a tardy operation. In reflex choreas excited or aggravated by local states such as adherent prepuce, nasal disease, etc. I have found it invariably necessary to treat the neuroses specifically after the exciting cause had been removed. In my experience there is no exception to this vicious habit tendency in all the neuroses. It is this fact which to my mind sufficiently explains the limitations of surgery in neurology as a means to the end of cure.[4] Remove the spicule of bone or the tumor or the clot in epilepsy, have the carious tooth extracted in neuralgia, circumcise in phimosis, free the adherent clitoris, remove adenoids, operate for nasal stenosis, correct the astigmatism or the eso- or exophoria in chorea or migraine but do not promise a cure from such procedure, and do not neglect the routine treatment which would apply in the idiopathic (so-called) cases. You will lessen the reproaches of conscience, and more important still, the reproaches of clients. In the treatment of tic douloureux the recognition of this habit tendency has a twofold therapeutic value and significance. First that already indicated in the preceding paragraph which bears particularly upon this affection because of the frequency with which the surgeon in this disease enters the domain of neurology. Nerve stretching, nerve section, or the more extreme and radical operation of Hartley or Krause is quite common. From personal experience, as well as a careful, conservative study of statistics, I desire to go on record as protesting most energetically against such procedures, one and all, except in most carefully selected cases, and always as a last resort, all other methods and measures having been faithfully tried and the worst results from operation being discounted by a worse condition beforehand. Be sure first that your patient has had the benefit of a trial of every other method and specific, empirical or otherwise, and sure that his condition cannot be made worse, no matter what the outcome. In all cases promise no more than this. You will find yourselves wise and fortunate in a direct ratio to your observance of this advice. Surgery to be effective, must be prompt and must anticipate habit tendency. Extirpation of the Gasserian ganglion does cure the pain, but at what risk and at what cost? There are many plans of treatment in this affection, any one of which may succeed in individual cases. A careful study of the personal equation as indicated in heredity, environment, temperament, physical habits, etc., may be and usually is decidedly helpful in determining the special plan you will follow in a particular case. Some patients bear anodynes badly, others are intolerant of stimulants. Assuming that you have eliminated local causes, constitutional states and reflex irritations, or that you have properly discounted them by treatment or otherwise, and your patient is still unrelieved, several more or less empirical plans remain. First as to the castor oil plan. I do not know how it proves effective, and your explanation is as good as mine, so we will not exchange theories. Daily doses of an ounce or two have occasionally been followed by relief. So far as I know no special indications exist which afford a guide as to the appropriateness for this method. If all other more legitimate methods fail, it should be tried. Dana's treatment with rapidly progressive and massive doses of strychnine I have found in a few cases marvelously happy in results. It should always be given a trial. The patient should be put to bed on a full nutritious diet with milk-cream mixtures as a special and forced feature. The strychnine should be given first—preferably hypodermically—in doses of $^1/_{40}$ gr. every four hours, the second day $^1/_{30}$ every four hours, the third day $^1/_{20}$, the fourth day $^1/_{16}$, the fifth day $^1/_{12}$. If no result is obtained by the end of the fifth day, it is useless and sometimes dangerous to pursue this plan further. I recall two cases, one referred to me by Dr. T. Kelley, treated at the Polyclinic Hospital, the other referred to me by Dr. Charlton Wallace, both promptly cured by this plan when everything else had failed. In both of these cases I was consulted, if I remember correctly, as to the method of operation and the selection of the operator, hope of relief from any other method having been abandoned.

There are other measures which may be tried of less constant or probable value, including aconite, gelsemium, colchicum, potassium, iodide and other drugs. I shall not burden you with presumably familiar details. My own plan, for which I claim some originality in conception, is as follows: Assuming all local and constitutional predisposing and exciting causes to have been properly antagonized and all clearly indicated etiological plans of treatment in individual cases to have been tried and found wanting, I adopt the following more or less specific course: First as to electricity. I always use galvanism and the continuous current introduced and withdrawn through the rheostat and guided as to quantity by the meter. One electrode, it makes no difference which, is applied back of the neck, the other (pliable, flexible) over the face affected. Both are bare Erb electrodes covered with wet towels thickly folded. Both electrodes should be as large as possible, diffusion of current at the contact surface being desirable. Irritating shock from interruptions or excessive currents should be avoided always and in all forms of painful neuritis. Two or 3 milliampères very gradually increased to 4, 5, or 6 for five minutes, the séances gradually lengthened to twenty or thirty

minutes, will be found to be safest and most effective. Mild currents with long seances is a safe general rule. Following this treatment the face is massaged gently with lanolin, and in several painful cases I have advised a face mask or hood to be worn day and night, lined with lambs wool fleece. With a full faith in my belief as to the importance of neurotic and neuritic habit tendencies, I apply this faith in works along the lines of the following theory and plan: Facial painful tic is primarily a disease of the fifth nerve. Very soon a sympathetic or associated implication of the seventh is induced through which the motor tic is added. The seventh forms the habit of ticking, so to speak, and this in turn keeps up the painful irritability of the fifth, a vicious cycle being the result, cause becoming effect and vice versa. Removal of the original cause of the painful neuritis of the fifth which started the motor tic of the seventh not being sufficient to break up the tic habit, I begin on the motor habit. I put the patient upon full doses of hyoscine hydrobromate, gr. $^1/_{100}$ to gr. $^1/_{50}$ twice or three times daily. I stop the tic by this means, and eliminate the continued source of irritation of the sensory fifth nerve. After controlling the tic, I attack the painful neurosis with one of the following combinations. Rx. sodii salicyl. gr. III, quin. sulph. gr. I to II, codeine gr. ¼ to I,—one such every three, four or five hours, or Rx. sodii salicyl. gr. III, heroin gr. $^1/_{10}$ or heroin alone, gr. $^1/_{25}$ to $^1/_{10}$ or codeine alone gr. ¼ to gr. I, or even two grains. The anodyne is reduced rapidly within a few days, and I then put the patient upon an active constructive tonic, always containing strychnine. I have tried various mechanical measures to control the tic, strapping the face with adhesive strips, painting it thickly with collodion, etc., in the effort to secure immobility, but with only occasional success. All such measures are inferior to the hyoscine. Gelsemium, colchicum and other similar drugs of ancient vogue act, when they act at all, through the same principle, in my belief, rather than specifically, and all are inferior, in my experience, to hyoscine. I have the records of four cases of tic douloureux in which this plan proved successful, almost every other method having failed to even alleviate. I have withheld details as they would needlessly lengthen this paper and additionally for the reason that they constitute the basis for a separate paper in preparation upon this special subject. Let me say in conclusion that it is in no one measure but by the careful observance of all details that the best results are obtained in the treatment of this affection.

Traumatic Neuritis.—A. B., aged forty-four years, American, merchant, of negative family and personal history. On February 16 last, in attempting to board a rapidly moving car he was jerked violently from his feet, still retaining his right hand grip upon the guard rail. Regaining his footing he jumped on the car, and in a violent rebound struck his right shoulder forcibly and viciously against the iron upright of the gate. He felt a severe local pain and tenderness immediately over the deltoid area, but not until two days later, the symptoms persisting, did he seek medical advice. Unfortunately either a superficial examination or a deficient knowledge led to the opinion that the entire trouble consisted of a muscular strain, with the correlated advice to use counter-irritant liniments, etc. Two weeks later his suffering and disability having steadily increased, he was referred to me. All discoloration and swelling had disappeared. Pain and tenderness on pressure over the acromion process and just over the joint anteriorly existed. The pain extended down the arm in a line along the outer surface, chiefly in the distribution of the circumflex to the elbow and below in the area of the ulnar. No pain below the wrist, but numerous paresthesiæ, particularly tingling and formication in the little and next finger. The response to the electric current was of the irritative character, but the polar formula was normal, no reaction of degeneration being present. There was considerable limitation of motion from pain and some actual diminution of power in the deltoid elevators and in both flexors and extensors of upper and forearm in resisting forced movements, with slightly diminished hand-grasp and slight beginning atrophy. The patient insisted upon attending to business daily, but agreed to wear the arm in a sling—my object being to thereby keep him constantly reminded not to use it. A lining of lamb's wool fleece was basted to the sleeve from the shoulder to wrist and daily massage inunctions of lanolin were ordered. A prescription each dose of which contained codeine gr. ¼, sodii salicyl. gr. III, quin. sulph. gr. I, was directed to be taken every four hours. Daily treatments with galvanism, one electrode 2 by 4 heavily protected back of the neck, the extended hand resting comfortably on the other (same size) was instituted. For the first three or four treatments a current of 3 or 4 milliampères carefully introduced through the rheostat was employed, the séances lasting some twenty minutes. Gradually, as the pain diminished, the current was increased to four, five and finally to ten milliampères. This patient was tardily responsive and seven weeks was required to effect a cure. Even now, as is often the case in neuritis, by the way, he is quite disagreeably reminded of past experiences after any unusual or depressing exertion or fatigue or by certain humid barometric and atmospheric conditions. In many cases for years afterward the victims of neuritis, toxic or traumatic, can foretell a storm with quite as much uncomfortable accuracy as the chronic rheumatic, and overexertion or fatigue from any cause brings a reminder in a sciatic ache or a brachial tire.

One aspect of this last subject demands special consideration because of its medicolegal bearing and importance. Traumatic neuritis the result of street-car and other accidents is an exceedingly common allegation in bills of particu-

lars in suits for damages. It is next, perhaps, in frequency to so-called railway spine. A large proportion of these cases are fraudulent, of course, but by no means all. It is quite as important in the interests of justice and humanity to protect the honest litigant as to expose the fraudulent malingerer. There are several quite nice points of diagnosis with which you should be familiar. In the first place the very important fact should not be overlooked that subjective symptoms are relatively valueless especially if unsupported by objective signs before judge and jury, while objective or demonstrable symptoms are positively convincing in medicolegal practice. Pain, weakness, paresthesia, anesthesia and analgesia are all subjective and may be simulated by the malingerer in extreme degree, and while of significance to the neurologist, are of but little weight to the layman in the jury box. Atrophy, especially if marked, altered deep reflexes, trophic changes in the skin, hair, nails, etc., and altered electrical reactions are objective and indisputable symptoms both in character and significance. Atrophy is to the trained expert much more certainly determined by the sense of touch than by vision.[5] The harpoon test with histological examination of the muscle tissue is advisable in doubtful and important cases. Alteration of the normal polar formula of Erb in the electrical response to galvanism is positive evidence of nerve degeneration, and therefore of organic damage.[6] Quantitative alterations to the faradic current are less positively significant alone, especially as to permanent injury. On the issue of electrical reactions alone I once won for a patient in a suit for damages in a case of traumatic neuritis. Sensory symptoms, no matter how extreme in degree, are always suspicious if unassociated with demonstrable motor trophic or electrical changes. In a recent medicolegal experience a litigant who was a malingerer of most aggravated autosuggestive type, claiming total loss of temperature sense, allowed a match to burn to total consumption resting on his bare skin without a quiver of muscle or the slightest sign of painful perception in anyway, the fact of malingerer plus self-hypnotism being easily demonstrable by a dozen tests which were successfully employed. True muscular atrophy, altered deep reflexes, properly tested, trophic disturbances and altered electrical reactions cannot be simulated, and are, therefore, of the utmost positive value in medicolegal cases.

Finally, and as a therapeutic summary, let me emphasize certain facts which will have been noted already perhaps by those who have read between the lines. First the importance of functional rest in all cases of neuritis often to the extent of mechanical enforcement; second, the value of forced nutrition, especially with fats, both constitutionally and locally, cream, butter and lanolin by inunction being always indicated; third, my great confidence in electricity and massage, neither of which, however, should be used empirically, both of which require in individual cases the utmost nicety of personal adjustment; fourth, the maintenance of an equable surface temperature in all forms of sensory neuritis, best attained by the use of lamb's wool fleece; fifth, the recognition of neurotic habit tendencies and predispositions which vary widely but should always be observed and never overlooked or disregarded and met with corrective nerve discipline, the method varying perhaps with each patient; sixth, recognition of the fact almost axiomatically true that all cases of neuritis except perhaps the traumatic and mechanical are associated with and often dependent upon states of altered metabolism and perverted nutrition to which recognition is logically correlated the necessity of tonic alterative and nutritional measures.

CLINICAL EXPERIENCES WITH THE ENLARGED PHARYNGEAL TONSIL.*

BY H. GRADLE, M.D.,
OF CHICAGO.

The first publication on adenoid vegetations by Wilhelm Meyer contained so complete a description and such rational ideas concerning treatment that subsequent observers have added but minor details to the subject. I, too, can only bring before you clinical fragments which may serve to fill out some gaps in our knowledge of the enlarged pharyngeal tonsil. I shall base my remarks on personal experiences with reference mainly to questions not fully settled, or still under controversy. A repetition of commonly accepted facts would be out of place.

Referring in the first place to the diagnosis of adenoid vegetations, allow me to discuss the significance of the facial appearance. The half open mouth, the thick upper lip, the thin and pinched nostrils and the sleepy look of the lower eyelids give the afflicted children a striking facial expression which Lange has aptly termed the adenoid habitus. As Meyer has pointed out this typical face has been reproduced by some sculptors of antiquity as well as in the painted portraits of historic subjects of the middle ages. While this stamp of face is highly suggestive of hypertrophy of the pharyngeal tonsil, yet it may in rare instances be due to other lesions. I can recall some 15 children in whom my presumptive diagnosis was not borne out by further examination. They were instances of chronic suppuration in comparatively narrow nasal passages with either a

* Read before the Otologic Section of the New York Academy of Medicine, Oct. 8, 1903.

normal, or, at any rate, a not much enlarged pharyngeal tonsil. In young children it is of course almost impossible to learn the exact site of the suppurative lesion. From the profusion of the discharge I inferred that it was due to a diffuse process. I have learned, however, that if there is any hypertrophy of the pharyngeal tonsil, however slight, accompanying this condition, its removal is essential for a cure. But the expectation of a striking improvement following the operation is not realized in such instances. Its benefits follow very gradually in connection with other treatment. Sometimes, too, though rarely, a septum deformity with enough diffuse hypertrophy to occlude both sides may simulate the adenoid habitus. But it is never produced by a one-sided obstruction.

On the other hand, the adenoid habitus is not seen in some children whose pharyngeal tonsil is sufficiently enlarged to be of decided clinical importance. It is true, however, these are but moderate enlargements producing disturbances rather by their state of inflammation than by their actual size.

It is but in a small proportion of instances that the obstruction to nasal respiration is directly due to the blockage of the post-nasal space by the hypertrophy. Such children can scarcely ever breathe through the nose and are not able to blow the nose. Most patients, however, breathe quite easily during daytime, at least, while being examined. Their real trouble begins only when they lie down, or during an acute "cold." Meyer suggested that the vegetations might vary in vascularity at different times. This is somewhat true, at least, in the case of the softer growths. The extirpated specimen is sometimes paler and apparently smaller than it appeared in the mirror during life. But repeated microscopical examinations did not show me a sufficient vascularity to account for any important variation in size according to the congestion of the vessels. I was hence led to attribute the greater obstruction during sleep to turgescence of the posterior ends of the turbinals—at least, the inferior; perhaps, too, the middle. This explains the fact that even after the most satisfactory operations it may take a few days before nasal respiration becomes normal, for the wound still keeps up the reflex turgescence. As you know, it does sometimes take weeks before the full benefit is realized. This view has also been supported by rhinoscopic observations on young soldiers by Barth, who found enlargement of the posterior ends of the turbinals more numerous in proportion to the size of the enlarged pharyngeal tonsil. In a small number of children I have been able to see the distended turbinals filling the posterior choanæ.

The variable degree and duration of turbinal turgescence explains likewise why the characteristic adenoid "dead" voice is not equally pronounced in all patients. It is invariably present in all large hypertrophies, but when the tonsil is not very large relative to the size of the upper pharynx the absence of resonance depends on the amount of occlusion of the choanæ by the swollen turbinals. Hence, a person without adenoid enlargement may temporarily speak in a typical manner during a severe coryza. Incidentally I may remind the audience how well Dickens has portrayed the adenoid voice in his character Barney in Oliver Twist.

The inattention or want of mental concentration of adenoid children which Guye has termed "aprosexia" seems to depend entirely on the size of the hypertrophy, and not on the obstruction by vascular distention. I have not met with it in over 15 per cent. of my cases, and these were all instances of large tonsils. It is, however, by no means present in all children with large adenoids, and its mode of occurrence is hence not clear.

Unless one has personally watched children with pronounced obstruction during sleep, it is difficult to realize how much disturbance this lesion engenders. The restlessness and tossing of these little patients is sometimes pitiable in the extreme. Frightening dreams, night-terror and nightmare are more common than is ordinarily stated. I have known two instances of asthma in children to cease after removal of adenoids, but I was not able to observe either one long enough to speak of a permanent cure. I can record, however, the relative frequency of cough as a reflex symptom in instances in which no bronchitis was present, basing the statement, of course, on the prompt disappearance of the cough after operation. In most instances, however, the cough present is really due to a subacute bronchitis secondary to the pharyngeal lesion. My experience agrees also with that of Groenbeck regarding the frequent coincidence of enuresis with adenoids. In rare instances the habit ceases promptly after operation; oftener, however, it disappears very gradually. Again, in a few cases the incontinence did not seem to be benefited by the removal of the tonsil.

It does not seem to me to have been sufficiently emphasized that the most mischief started by adenoids results from attacks of inflammation so frequently occurring in the tonsil when enlarged. These inflammatory spells, often but subacute from the start, extend to the nasal passages, to the ears, and not rarely descend into the bronchi. The enlarged pharyngeal tonsil is not necessarily or continuously inflamed. Like large faucial tonsils, it may be fairly pale, though never as pale as a non-inflamed faucial tonsil. During such periods there are no symptoms except those due to the size of the hypertrophy. Moreover, there is no purulent secretion during this quiescent period. That it is not merely the presence of the pharyngeal hypertrophy, but that it is the inflammatory attack starting there, which accounts for the involvement of the bronchial tubes and of the ears can readily be learned from carefully taken clinical histories in suitable cases. From observant parents we can learn that the bronchitis or the acute ear disease is the sequel of a "cold" first noticed in the nose or throat. While this in-

flammatory origin is quite evident in the case of a primary or a recurrent purulent otitis, it is commonly believed that the ordinary form of impaired hearing resulting from adenoids—the so-called Eustachian catarrh—is produced by pressure against the Eustachian orifices. This view is not borne out by my experience. In the rhinoscopic view, whenever feasible, the lymphoid growth is usually found quite distant from the Eustachian region. Hearing is not necessarily impaired by adenoids, even when quite large. The Eustachian obstruction may begin any time after the growth has long been known to exist, and in favorable instances the ear symptoms sometimes disappear spontaneously when the inclement season is over. Occasionally one can get the definite history of an inflammatory attack in the nose preceding the impaired hearing. As a rule, however, this form of ear involvement begins so insidiously that the history is not decisive. As we all know, the prognosis for the hearing is on the whole quite favorable in simple Eustachian catarrh. It has seemed to me, indeed, as if the danger to the ears had been somewhat overstated in literature. Yet I am not unmindful of the fact that in relatively rare instances Eustachian obstruction resulting from adenoids may lead to mucous exudation and ultimately to proliferative changes in the middle ear. We must also take into account that adenoids are found in a large majority of deaf-mutes, and that in those subjects their presence is often an important factor in the etiology of the graver and irreparable lesions.

The relation of adenoids to eye affections has not received quite the attention it deserves. Of children suffering from phlyctenular keratitis a large majority have a hypertrophied pharyngeal tonsil, although extremely large growths are rather exceptional. Within the last two years I have followed the practice of removing the adenoids in all such instances, even when they had caused no disturbance beyond slight impairment of nasal permeability. While the erratic course of phlyctenular keratitis does not permit dogmatic statements, I must still insist that my impressions regarding this treatment have been very favorable. In cases which had previously been properly treated by others, but without attention to the adenoids the operation has so often changed promptly the course of the eye disease, as to leave little doubt regarding the pernicious influence of the pharyngeal lesion.

Any observer with moderate experience cannot fail to notice the striking influence of adenoids upon the general nutrition in some instances. The majority of our juvenile patients, it is true, enjoy good general health and suffer only from local symptoms. But in about 20 per cent. the weight and even the growth are below par, the children are frail and anemic. All this malnutrition is, as a rule, corrected, and often to a striking extent, by operation. This influence on nutrition does not depend on the size of the growth. Quite often a relatively small tonsil has escaped detection on account of but slight obstructive symptoms, and yet the child will pick up wonderfully after its removal. I have many records of a gain in weight of 10 to 20 per cent. within half a year following the operation. The interfered breathing and disturbed rest can scarcely account for this effect upon nutrition, as the latter is not proportionate to the former. It seems rather as if some adenoids exerted a poisonous influence upon the system. I need but remind you of the researches of Lichtwitz and Sabrazès, who found an inversion of the percentage formula of white blood-corpuscles together with a high anemia the common rule in adenoid children. Personally, I have also found anemia improving rapidly after operation.

As children advance in age the proportion of immediate and complete results following a satisfactory operation is somewhat lessened as compared with younger subjects. I attribute this to hyperplastic lesions in the upper air passages often induced by adenoids in the course of time. This influence is best observed in the faucial tonsils. Hypertrophy of the latter without adenoids is not common, while conversely moderate adenoids without abnormal faucial tonsils are much more often met with. Decisive of the relationship between the two is the frequent observation that after the adenoid operation the faucial tonsils lose their irritated appearance and shrink slightly in size. Hence, the indications for their removal disappear not rarely after the pharyngeal tonsil has been taken out. Similarly I have noticed that among children with septal hypertrophies there are but few without adenoids. As these septal irregularities, apart from pure deflections, are not common until long after puberty, the prevalence of adenoids cannot but signify an etiological relationship. I will refer, too, again to the statistics of Barth, showing the effect of unremoved adenoids in causing enlargement of the turbinal extremities.

The cause of the abnormal growth of the pharyngeal tonsil I can only find in repeated attacks of coryza in predisposed subjects. Whenever I have been able to observe personally, or to trace reliably the development of adenoids, it was always the same history. The baby's first disturbance was a severe "cold" in the nose, with obstruction and purulent discharge. The attack subsided but the interference with nasal breathing remained, and became intensified with every subsequent coryza. As far as I have been able to observe, the morbid growth begins in the first or second year of life, though often it does not reach an embarrassing degree until a few years later. If, however, no enlargement has occurred within the first three of four years I have all reasons to believe that there is no predisposition to lymphoid hypertrophy. I have known a few instances of acute inflammation of the pharyngeal tonsil in older children who had previously had normal nasal breathing. The tonsil was swollen to an extent simulating extreme adenoid hypertrophy. Yet it regained its normal size in the course of some weeks and left the nasopharynx

unobstructed. I have never met with congenital adenoid hypertrophy and greatly doubt its possibility. Regarding the nature of the predisposition to hypertrophy we have as yet no knowledge. To some extent it is hereditary. For it is quite patent that in some large families there are more instances than could be accounted for by accident, while in others it is conspicuously absent.

The predisposition to lymphoid enlargement is marked in instances of degeneracy. Various observers have noted that large adenoids are almost the rule in imbecile children which I can confirm in my limited experience. Among some 1,200 cases which I have operated there were about 15 to 20 children—over 1½ per cent.—who while not imbecile, were backward mentally to an extent beyond what could be considered "aprosexia." As far as I could learn they were little or not benefited mentally by the operation. This is a larger proportion than would be found in children without adenoids. Again the proportion of adenoids in deaf-mutes is strikingly larger than in normal children. While this lesion is in some instances a factor in the causation of the labyrinthine lesion through extension of disease of the middle ear, it is in the majority of deaf-mutes but an associate evidence of a degenerate tendency. It has also been stated that adenoids are the rule in children with cleft palate. Of six cases, however, which I have examined three only had enlargement of the pharyngeal tonsil.

An important and not fully solved problem is the relation of adenoids to scrofula, as in apparently scrofulous children adenoids are much more common than in others. If we use the term scrofula in its older clinical but rather vague sense, viz., referring to a poorly nourished, pale child with adenoid stamp of face and liability to purulent otitis, it coincides with the picture due directly to the enlarged tonsil. To a certain extent the appearance of scrofula is thus produced or at least simulated by the adenoid hypertrophy and ceases after its removal. But the trend of modern research suggests that true scrofula is more than this, that it is really the result of slight chronic poisoning of the system from some tubercular focus in lymph glands. As a rule, the enlarged pharyngeal tonsil cannot itself be accused of being this focus. For a large number of microscopical examinations by different observers have shown that about 95 per cent. of adenoids contain nothing suspicious of tuberculosis. It is only in some five per cent. of specimens that caseating tubercles are found. I have had 15 successive tonsils examined showing two times tuberculous infiltration, a proportion which is no doubt accidentally large in so small a series. It is striking that tuberculosis of the tonsil does not reveal itself either during life or on gross view of the extirpated growth. The concordant opinion of all who have followed their cases is that the tonsillar tuberculosis is rarely if ever primary. Lewin has shown, too, that in tuberculous cadavers tubercles are found about as often in the pharyngeal tonsil when of normal size as when enlarged. Hence we can consider actual tuberculosis of the pharyngeal gland only as an exceptional occurrence. It is, however, worth noting that adenoids are so often the cause of enlarged lymph glands on the back of the neck. That many of these glands are tubercular has been shown both by autopsies and by diagnostic tuberculin injections. Hence the suspicion is at least tenable that after all the enlarged pharyngeal gland may be the gate of invasion of the tubercle bacillus, even though the latter does not often cause local manifestations in the tonsil itself.

There can be but little dispute regarding the indication to remove every enlarged pharyngeal tonsil that causes disturbance by its enlargement or its periodic attacks of inflammation. Regarding the size of the normal tonsil we cannot accept the dictum of the anatomist, as his observations do not decide whether a given specimen is or is not strictly normal. On the basis of rhinoscopical examination I regard a tonsil as morbidly enlarged whenever it protrudes abruptly above the level of the surrounding mucous membranes, no matter how little. But a minor and stationary hypertrophy in a relatively spacious pharynx produces no symptoms and hence calls for no interference. Incidentally, I may remark that all the older illustrations of adenoids during life with exaggerated coxcomb and stalactite appearance are fanciful, for nothing like this is seen in completely extirpated specimens.

A trial of almost all instruments for the removal of adenoids has led me to decide definitely in favor of Schütz's guillotine-shaped pharyngotome as the best. I have modified it slightly in construction and especially in the shape of the handle, and can now report nearly five years' experience in about 250 operations. As now made it is very substantial and can be perfectly cleansed and sterilized by dipping it into boiling soda solution. The knife blade is apt to break when moved to and fro very many times in succession, but can be quickly replaced. A break during operation, which has occurred to me but once, led to no trouble beyond a second introduction. I consider its use the most thorough and quickest of all operative methods. A similar strong endorsement of the original Schütz instrument had previously been given by Hessler after trial in 100 operations. The ordinary pattern is applicable in all children above three to four years of age, while a smaller size can be used in younger subjects. It can slide round good-sized enlarged faucial tonsils and is only hindered by an unusual degree of their hypertrophy. With the head thrown back, the shoulders forward, the lower jaw well depressed, the guillotine pushed firmly upward and backward, the entire tonsil is bound to be cut off in one sweep. Unless swallowed, which is a rare accident, the specimen demonstrates the correctness of the diagnosis and the thoroughness of the operation. A slip, as sometimes happens with the Gottstein knife, is

almost impossible. As often as I have reinserted the instrument a second time, I have usually failed to bring away any more remnants, provided I pressed firmly enough in the first instance. Examination after healing shows occasionally a small fringe of adenoid tissue next to the upper rim of the choanæ. These remnants were of sufficient size to permit or demand a second operation but twice in over 200 instances. The hemorrhage is the same as with any other operative method, but it does not last as long. In my former experience with my older pattern of forceps or with the Gottstein knife a return and persistence of hemorrhage occurred in about one per cent. of cases. I have been able to trace such persistent bleeding to tags of partially detached tissue. As the adenotome makes a clean sweep, this danger is removed.

The quickness of the operation has made narcosis entirely unnecessary in my practice. I employ anesthesia only when the faucial tonsils are to be removed in the same sitting, or when the parents demand it. While we cannot anesthetize completely by means of cocaine, still, the local effect of cocaine aided by adrenalin reduces the discomfort to such an extent that I cannot but consider narcosis the harsher procedure for a child. The timely warning by Hinkel has shown the danger of chloroform in adenoid children to be so great that it should not be employed. As far as I can learn from literature and my small experience, ether is not more dangerous to these subjects than to average children, but on account of its more unpleasant action it has not been used as much as chloroform. For a simple adenoid operation nitrous oxide gas is undoubtedly the safest and least objectionable if an anesthetic is to be used. But I can only repeat that outside of multiple (faucial) tonsillotomy the adenotome enables the operator to do his work more quickly, with equal thoroughness and with no more harshness on the wide-awake child than under narcosis.

While operating with my former forceps I found it necessary to do a second operation after reexamination during the second week in nearly one-quarter of cases. With increasing practice this number diminished, but especially so by beginning with the Gottstein knife and following with my forceps if the removed specimen did not seem to include the whole tonsil. The adenotome, however, has but twice failed in reaching from the anterior to the posterior end of the growth. Undue stress it seems to me has been laid upon the extension of adenoids into Rosenmüller's fossæ. Ordinarily the base of the growth does not extend quite so far laterally, though soft vegetations sometimes spread out along the surface. In rare instances lymphoid tissue really fills the fossæ after the tonsil has been removed. This can only be taken away with a small curette, provided irritation of any kind indicates its removal. Large, wing-like masses of lymphoid tissue which in rare instances descend from the fossæ to below the level of the soft palate I have found to be infiltrated reduplications of mucous membrane independent of adenoids proper, as they occur sometimes without the latter.

For the removal of remnants of the tonsil left by an incomplete operation I have found the cold snare the most convenient instrument. I use a straight snare through the mouth with the wire loop bent upward. This manipulation causes so little pain that repeated insertions are always tolerated by manageable children.

Relapses of adenoid growth I have only seen after incomplete operation, as indicated by the history or the asymmetry of the growth. Their probability seems to depend on the amount of tissue left as well as on the youth of the patient and his susceptibility to inflammatory attacks.

THE SURGICAL TREATMENT OF DYSMENORRHEA.

BY WM. E. PARKE, M.D.,
OF PHILADELPHIA.

When asked to read a paper on the surgical treatment of dysmenorrhea, an aphorism of student days respecting diseases of the ear at once came to my mind, namely, diseases of the ear are divided into two classes, those that are cured by the use of the Politzer bag and those that are not. In a like manner I might suggest that dysmenorrheas may be divided into two classes, the one curable by dilatation and curettage, the other not.

The causes of dysmenorrhea having been set forth by my predecessor, I will only allude to the symptomatology to indicate the type for which operative measures promise relief.

The rôle which dilatation and curettage plays in the operative treatment of dysmenorrhea, you will perceive, is an important one, although operations of greater gravity are demanded when this symptom is secondary to certain pathological changes.

The symptom of true obstructive dysmenorrhea is *pain* which has the cramp-like character of labor pains. It may follow an operation, or examination may disclose the presence of a new growth. The operative treatment of this condition will consist, of course, in the removal of the cause. If it be a fibroid, remove it if feasible, amputating the cervix, if necessary, or do a hysterectomy. When obstruction is due to cancer the disease is usually so far advanced as to be incapable of complete removal, and we must be satisfied with scraping out the canal. If cicatricial contraction following operation be the cause, dilatation should be done, and curettage is in order, for the endometrium is always diseased under these circumstances.

The small anteflexed uteri are usually underdeveloped. Pain in this class of cases was formerly thought to arise from obstruction due to angulation of the canal. This is probably an error. Dilatation sometimes benefits these cases, but they are not promising ones for cure by this means.

Membranous Dysmenorrhea is attended by pain not unlike labor pains, which come on with the beginning of the menstrual period and continue with increasing severity until the membrane is expelled. It is in this particular an obstructive dysmenorrhea, and its surgical treatment should consist in a wide dilatation, curettage and application of pure carbolic acid to the endometrium. This expedient affords relief from the severe pain for a time and occasionally cures the disease.

Spasmodic Dysmenorrhea is characterized by pain which is cramp-like, and often of great severity, causing the victim to toss about, sweat, and sometimes vomit or even faint. It is paroxysmal and usually of short duration but rarely may be prolonged sufficiently to lose this distinctive sign. When severe, it is not localized to the uterus, but fills the whole pelvic zone, and may or may not come and go with the menstrual flow. Recumbent posture does not favorably affect the pain, and patients often express themselves as relieved by alcohol. A fairly large percentage of this class of patients are sterile. Physical examination of these cases, after some years of suffering will show a somewhat hypertrophied uterus.

The simple operation of dilatation and curettage finds its greatest field for usefulness in this type of cases. It is probable that the internal os in this condition is unusually sensitive and acts as a sphincter, and that forcible dilatation paralyses or lacerates some of the muscular fibers and thus relieves spasm, just as the dilatation of the sphincter ani muscle relieves spasm. The drainage canal is thus widened and secretion and especially clots are expelled with less muscular effort.

Congestive Dysmenorrhea is marked by pain of quite a different character from the preceding. Here it is more or less constant and precedes the flow by some days or a week. It may be simply an exaggeration of the aching that so commonly accompanies menstruation, or be severe enough to confine the patient to bed. It is worse at the beginning and improves toward the end of menstruation. It does not cause tossing about, fainting or vomiting, and is improved by the recumbent posture. The seat of pain is the pelvic area, but it is so often localized to the region of the left ovary, or both ovaries, as to give rise to the name of ovarian dysmenorrhea. Congestive dysmenorrheas are often dependent on pathological changes in the uterus itself, or its appendages, such as chronic metritis or endometritis, retroflexion, fibroid tumors and inflammation, or prolapse, of the ovaries and tubes. Congestive dysmenorrheas pure and simple do not require surgical treatment for their cure; but when they are secondary to the conditions above mentioned, some operative measure affords the only substantial relief in our hands. Thus a retroflexed uterus should be not only dilated and curetted, but the organ should be restored to the normal position by an appropriate operation such as shortening the round ligaments or hysterorrhaphy. When diseased appendages are the cause of the pain, its cure may depend on their removal. If fibroid tumors are present, their removal is to be advised, although dilatation and curettage will sometimes greatly ameliorate the condition, and should be tried where consent for the greater operation cannot be obtained.

The text-books mention other varieties of dysmenorrhea, for instance, neuralgic dysmenorrhea and rheumatic and gouty dysmenorrhea, which I mention only to remark that they do not come within the sphere of operative treatment and hence not within the scope of this paper.

The above-mentioned kinds of dysmenorrhea, I need scarcely say, are not always found conforming to a single type, but are sometimes blended, the symptoms of one class predominating over those of the others. Thus we may have a dysmenorrhea partly congestive and partly neuralgic—or spasmodic and congestive, and so are led not to give too rosy a prognosis in many instances after dilatation and curettage, for it is not a universal cure.

There is a dysmenorrhea or a condition associated with dysmenorrhea, which I think of sufficient importance to merit a special paragraph. I refer to ectopic pregnancy. A characteristic history is as follows: The patient misses one or more periods and may suffer from slight pelvic pain. Suddenly she is seized with severe pelvic pain and metrorrhagia with perhaps the discharge of membranes. This sometimes continues for days or even weeks, if the patient survives. She thinks it is simply irregular menstruation or perhaps a miscarriage; and not rarely the true nature of the case is overlooked by the physician who does not make the necessary examination. The operative treatment consists in the removal of that appendage which is the seat of the pregnancy.

Before describing the technic of the operation of dilatation and curettage, I consider it important to point out the contra-indications to this simple procedure. One should never dilate and curette a uterus whose appendages are known to be diseased, unless at the same time an appropriate operation is done upon the appendages; that is, when a physicial examination shows the presence of masses on either side of the uterus or adhesions of that organ, or of the tubes and ovaries.

Technic.—The operation should be conducted with the same antiseptic care as operations on other parts of the body. It is, therefore, necessary to anesthetize the patient; to wash the vulva and vagina carefully with soap and water, and to follow this with a bichloride or other antiseptic solution.

After introducing a speculum to retract the perineum, seize the anterior lip of the cervix with a volsella forceps, to draw down the organ and hold it firmly, while the smaller sized Goodell or Walthen dilators are introduced into the uterine canal (using previously, if necessary, a uterine sound to find the direction of the canal).

Stretch the canal sufficiently to introduce the larger sized dilator. Continue with this instrument to stretch the canal, either rapidly and in all directions or more slowly in one direction (Goodell's method) until, in a nulliparous woman, the blades are three-quarters of an inch apart, or in a parous woman they are as much as an inch or an inch and a quarter apart. The dilated canal will now admit a curette without undue force. This should be a sharp one (I know of no use for a dull curette). It should be grasped firmly by the thumb and fingers so that the amount of force used can be delicately determined. The whole endometrium is to be carefully scraped until the contact of the instrument with the more substantial underlying muscular structure becomes audible and communicates a distinct thrill to the operator's hand. That part of the endometrium which lines the uppermost part of the cavity is best reached by the curette forceps, an instrument which is a combination of the Gross stone forceps and the postnasal curette forceps. Following this the débris is to be washed out with sterile water through a two-way catheter, or wiped out with dry gauze

While I have alluded to this as a simple operation, I do not want to leave the impression that it is wholly unattended with danger. For in the hands of the most experienced surgeons, perforation by the dilators or curette has repeatedly occurred; and in the hands of less experienced operators serious damage to other abdominal viscera has been recorded.

It is, therefore, not to be undertaken without a physical examination to determine the absence of contra-indications, and should be done with the greatest attention to antiseptic details, and with judgment and care to avoid accidents.

THE DANGERS OF INFLATING THE STOMACH WITH CO_2 GAS; ITS DIAGNOSTIC VALUE. REPORT OF THREE CASES WITH AUTOPSIES.

BY MOSES BEHREND, A.M., M.D.,
OF PHILADELPHIA.

It is a remarkable fact that in a vast amount of literature reviewed not one case has been reported in which death can be directly ascribed to the use of carbon dioxide gas in inflating the stomach. The test has been used extensively in the last decade by many observers. Von Ziemssen and Mankopf have been strong advocates of this method; Mankopf and von Frerich being the first to use it. They advise it because of the sudden distention of the stomach which this gas causes, whereby the contour is easily outlined and the various displacements and morbid processes are thus more readily diagnosed. This is undoubtedly true, but the dangers following this explosion must be attributed to the sudden evolution of gas over which we have no control.

Referring to the CO_2 method of inflating the stomach Ewald says: "These methods suffer from the disadvantages that we have no control over the amount of gas produced after the salts have been introduced into the stomach or intestines, that disagreeable accompanying symptoms frequently arise from the irritation of the CO_2 gas upon the walls of the stomach or intestines and that, even though varying quantities of gas are needed for different persons, the degree of tension produced cannot be regulated at will or increased at a given moment."

Ewald again, in quoting Oser, Meinert and Riegel, states that these men have not noted any unfavorable results from this method. Schütz believes that a better examination can be made with CO_2 gas than with the inflation of air, on account of the sudden distention produced by the former procedure. Opposed to him are Runeberg and Oser, who inflate the stomach with air by the passage of the stomach tube. They believe that in this way the degree of the distention of the stomach can be well regulated. No one will doubt this, but this method is not without its dangers and disadvantages. The passage of the stomach tube is the main objection, especially with private patients.

The use of CO_2 gas in office practice for diagnostic purposes was recently mentioned by Elsner. Steele uses both to a considerable extent at the University Hospital. The practice of using these methods in the office and dispensary should be condemned.

The disastrous results obtained from the use of CO_2 gas for diagnostic purposes has led the writer to report the cases under his observation while interne at the Philadelphia Hospital. The method under discussion is certainly of diagnostic value as in all the cases the situation of the disease was located before death.

A diagnosis being difficult in the three cases led to the employment of CO_2 gas. The usual technic was followed. About one dram each of tartaric acid and sodium bicarbonate was dissolved in half a glass of water. The sodium bicarbonate was given first, followed immediately by the tartaric acid solution. Almost instantly a swelling was noticed in the epigastric region in one case. In all three there was a sense of oppression followed by depression and a condition resembling shock.

In the case just mentioned hemorrhage resulted, causing death of the patient twenty hours after its use.

Case I.—M. P., aged sixty-eight years; admitted to hospital May 2, 1901. She was sent from the out ward with a history that she had been in bed at intervals for several weeks and that she vomits after taking food. The chief complaint on admission to the hospital was weakness and inability to keep anything on her stomach. Her family history was unimportant. She had malaria, yellow fever and rheumatism. Menstruated at thirteen years. Always regular. Menopause not known. The present trouble extends over a period of twelve months. At the time I saw the patient she had symptoms referable to the stomach. She was well nourished but pallid. Marked

cardiac arrhythmia was also present; this was absent on admission to the hospital one year later. Now she vomits immediately after eating, appetite gone, marked eructations of gas, bowels variable, headache, vertigo, palpitation, some dyspnea, and pain across the epigastric region.

Physical Examination.—Patient is a very much emaciated woman; skin universally wrinkled; chest capacious, costal angle obtuse; breasts atrophied, though pendulous; abdomen scaphoid. Heart sounds are weak, though rhythmical. Lungs are emphysematous. Liver and spleen apparently normal in outline. Tenderness in epigastric region. No mass can be felt.

May 7, 1901. She is getting gradually worse, vomiting everything eaten. No blood is noticed. Drugs do not relieve her at all.

May 12, 1901. No diagnosis having been made, it was decided, after consulting my chief, Dr. W. E. Hughes, to use the CO_2 gas to inflate the stomach. Immediately after its use the patient was greatly distressed, tossing her head from side to side and making special efforts to throw off the gas. About half an hour afterward she vomited a quart of blood and at irregular intervals during the course of twelve hours large quantities of blood were ejected. Patient lived twenty hours after taking the seidlitz powder. At the time of her death she was exsanguinated.

AUTOPSY BY DR. FLEXNER.

Pathological Diagnosis.—Ulcer of stomach, hemorrhage, general anemia, adhesive pericarditis, chronic nephritis, small, granular kidney, atrophic cirrhosis, cholelithiasis, nephrolithiasis, acute peritonitis, cyst of ovary (left). That part of the autopsy relevant to the stomach condition will be described. Loops of intestine are distended, dark in color, tissues of lesser omentum are infiltrated with small recent hemorrhages. Stomach. Old adhesions on left side between fundus and spleen and between spleen and diaphragm. Stomach is not dilated, greater curvature shows a series of fine linear ulcerations. These are arranged in a radial manner about the esophageal orifice and average 4 cm. below the orifice. They extend into the submucous coat. They vary in length from 3 to 4 cm.; and in width from 4 to 6 cm. Their edges are elongated and slightly puckered. In the middle of base of one a small mass of necrotic tissue is seen. In addition to these there occur on the anterior surface of stomach about the middle of the lesser curvature, but near the esophageal end, a recent ulcer on which a recent clot sits. This ulcer, as far as can be made out, is triangular in form, measuring at its base 4½ cm. Its edges resemble those already described. At the apex of this triangle it is surrounded by two semicircular lines of ulceration; the larger one at the right extremity connected with an anastomosing ulcer also linear in form which is placed a little nearer the pyloric extremity. The serous coat corresponding to the necrotic focus is covered with fibrin. On moving this clot the interior of the stomach is reached. Necrotic serosa only separates it from the lesser cavity of the peritoneum. The ulcer is 4 cm. from the esophageal and 11 cm. from the pyloric extremity. The remainder of mucous membrane, especially about pylorus, is mammillated.

The immediate result, as shown by the post-mortem record, was the rupture of a blood-vessel at the base of an ulcer from which fatal hemorrhage ensued. The fact that this happened in the first patient on whom the CO_2 test was tried was an unfortunate circumstance, but believing it to be an unavoidable accident it was determined to give the test a fair trial.

It was hardly expected that in a patient almost seventy years of age an ulcer should be found. The vomiting occurring immediately after eating should probably have pointed to an ulcer of the stomach but in another case in which the same symptom was present a different condition was found.

Case II.—G. S., male, aged seventy-three years; was admitted to hospital June 21, 1901. His chief complaint was vomiting after eating. His family history was negative.

Previous History.—He had the usual diseases of childhood. Typhoid fever three years ago. No venereal disease. Always been a user of beer.

Present History.—Eight years ago trouble began with vomiting immediately after eating. This has persisted up to the present time. Can retain nothing except a little hot milk. Has no pain in stomach; no vomiting of blood.

Physical Examination.—Patient is an old man very much emaciated, a German. All bony outlines are prominent. Pupils equal and react to light and accommodation. Tongue is pale, pulse irregular in volume, arteries compressible though thickened. Chest well formed but extremely emaciated. Abdomen is scaphoid. Lungs are hyperresonant; vesicular murmur and vocal resonance diminished. Heart. Outline difficult to obtain on account of hyperresonance; sounds at apex show a slight systolic murmur. Abdomen. The only thing felt is a prominent pulsating aorta. The muscles in the neighborhood of the stomach are very rigid rendering palpation unsatisfactory. Liver dulness limited to a narrow zone of two inches.

June 28, 1901. Patient is getting weaker, vomiting almost everything eaten. Dulness at interscapulovertebral space. Esophageal bougies pass easily; larynx apparently normal. A small tumor is seen on pharyngeal wall.

June 29, 1901. To-day the CO_2 test was tried on patient. A large quantity of froth and a little blood were vomited or rather regurgitated immediately. After giving it the stomach was not distended. The patient was extremely prostrated immediately after its use and never rallied. He died on the following day.

AUTOPSY BY DR. PEARCE.

Pathological Diagnosis.—Carcinoma of the esophagus and stomach, cholelithiasis, perichole-

cystitis. The stomach is small, distended with a little gas. At the junction of the esophagus and stomach a hard mass may be felt externally. Esophagus shows agonal digestion in its middle part. Beginning 5 cm. from the cardiac orifice there is a mushroom-like tumor, soft in consistency, taking in entire diameter. This is continuous with a similar growth extending to the stomach at orifice involving the entire circumference. The central portion of both tumors is ulcerated and the ulcers are surrounded by this soft, elevated, mushroom-like growth. Surface is much pigmented and of a slaty color.

The fact that the gas generated by the CO_2 did not distend the stomach fixed the diagnosis above or at the cardiac end of that organ, and the clinical diagnosis of carcinoma of the esophagus and cardiac end of the stomach was made during life.

The diagnosis of the situation of the lesion in the previous and the next case to be reported was made because of the absence of epigastric fulness that follows the ebullition of the CO_2 gas in the stomach.

As it is always desirable to make a diagnosis during life this is an important point, but the danger connected with its use offsets its utility. To illustrate the localizing power of CO_2 gas the next case is a striking example.

Case III.—C. M. aged fifty-two years. Admitted April 12, 1901. Chief complaint, pain just below and to the left of the sternocostal angle. Nothing is known concerning his family history.

Previous History.—For years patient has had a feeling of discomfort at the point above mentioned. After eating there would be a sensation as of the esophagus being dilated. Ever since an attack of influenza six weeks ago his trouble has been exaggerated. Lost much weight. Appetite very poor.

Physical Examination.—Patient is very thin. Sclera is of a muddy color, tongue is brown. Pulse regular. The chest is spare and musculature poor; all bones prominent. Abdomen is retracted and of doughy consistency. At intercostal angle there is tenderness but no mass can be made out, the pulsating aorta is easily felt. Right rectus muscle very rigid. Heart and lungs show nothing abnormal.

April 22, 1901. Emaciation extreme, voice hiusky—increasing in intensity from day to day. Examination by Dr. Gleason shows paralysis of vocal cords and chronic inflammation of the mucous membrane.

April 26, 1901. Patient is getting weaker, taking very little nourishment, vomiting a quantity of black fluid with clots. Microscope showed latter to be blood.

May 19, 1901. No change since taking of last note except the increasing emaciation and weakness, no vomiting. The CO_2 test was given today, no change noted in the abdomen, stomach apparently not affected. The distress noted in Cases I and II was seen here. The patient seemed dazed after its administration and he was in a more or less semiconscious condition till the time of his death on May 24, 1901.

Clinical Diagnosis.—Carcinoma of the esophagus.

AUTOPSY BY DR. PEARCE.

Pathological Diagnosis.—Dilatation of esophagus, suppuration of tracheal lymph-nodes, chronic diffuse nephritis, chronic pleurisy, edema of lung, chronic splenitis, atrophy of right testicle. Esophagus dilated throughout entire extent, 31 cm. Greatest dilatation at cardiac end with circumference of 18.3 cm., 4 cm. in middle, 15 cm. below the beginning, circumference is 12.5 cm.; mucosa thickened, showing irregular, elevated, grayish, finely granular plaques between, which are depressed smooth black areas. This appearance is uniform throughout the entire extent. The glands about the trachea and esophagus are greatly enlarged and contain soft puriform, almost cheese-like, substance. The largest of the softening glands measure 5 x 3 cm. There is no calcification and they do not suggest tuberculosis; no condition is found which would explain dilatation of the esophagus by traction. The recurrent laryngeal nerve courses over the enlarged glands.

All these cases are interesting on account of the pathological findings; the dissimilarity of lesions with like symptoms is unique; the fact that vomiting did not occur immediately after eating in Case III is on account of the extreme pouch of the esophagus.

It must be evident from these observations that the use of CO_2 gas in inflating the stomach is a serious matter. It is infinitely more dangerous where there is disease of the esophagus and cardiac end of the stomach. This may be due to the pressure exerted within narrow limits. The test must be used, if at all, with discretion and the cases must be selected. The lives of all the above patients were undoubtedly shortened.

I wish to extend my appreciation and thanks to Drs. Wm. E. Hughes and H. B. Allyn for their kind permission to use the cases, without which this paper could not have been written.

Sulphite of Sodium as Conservative Agent.—This substance is able to check the growth of bacteria in as weak a dilution as 0.05 per cent., but the best effects are obtained with 0.5 per cent. The bacteria are not directly killed, but are merely prevented from multiplying, and the normal color of the meat will be preserved. E. Altschüler (Arch. f. Hyg., Vol. 48, No. 2) does not think that the use of this chemical should be permitted by law; though it is relatively harmless, it will improve the appearance and remove the odor from meat which is really already in advanced putrefaction.

ON THE VALUE OF URETERAL CATHETERIZATION AND URINE SEPARATION WITH HEMOCRYOSCOPY AND URINOCRYOSCOPY IN SURGICAL DISEASES OF THE KIDNEY.*

BY WILLIAM E. LOWER, M.D.,
OF CLEVELAND, OHIO;
LECTURER ON GENITO-URINARY SURGERY, WESTERN RESERVE MEDICAL COLLEGE, CLEVELAND, OHIO.

Renal surgery has kept well apace with the rapid strides made in the surgery of other organs. However, the good showing in the surgery of the kidney has not been, as in many of the other instances, due so much to the improved technic of the operation, as to the better methods of diagnosis.

The splendid results in renal surgery, which are now being reported from all over the world, are encouraging in the extreme, and are splendid monuments to greater precision in diagnosis. To analyze briefly the causes of the high mortality rate of a decade or more ago, we find the principal reasons for the postoperative deaths to be (1) the congenital absence of a second organ, which is assumed to be present; (2) the degeneration of the organs, whereby a partial or total disappearance of the same has occurred; (3) a pathological condition of the other organ, which is of normal shape and size, but which is functionally more or less inert. To eliminate these factors from the causes of postoperative deaths is the object toward which the clinicians must direct their efforts.

How are we to diagnosticate the presence or absence of a second kidney? The methods formerly in vogue and still recommended by some, are inspection, percussion, palpation, and actinography. A mere mention of these methods is enough to show that none has any absolute worth. All are unreliable, and at times highly inaccurate. Much more reliable are the methods of cystoscopy, ureteral catheterization, and lastly the exploratory incision.

When ureteral catheterization is possible, a definite demonstration of the presence of a kidney can be established, especially if a stilet be used and an X-ray picture taken. If catheterizing the ureter be not possible, then a separation of the urine by one of the different separators should be practised and in this way establish the separate flow of urine.

Having determined the presence of a second kidney, how can we best determine the functionating capacity of that organ? By the functionating capacity of the kidney is understood the power to elaborate its peculiar excretion. If there is to be a cutting operation on a kidney, it is not enough to know that there exists a second kidney, but it is absolutely necessary to know that there is present a second kidney in good enough condition for the preservation of the patient. In order to establish this it is necessary to obtain the urine from each kidney separately. For this purpose two methods are known, the direct and the indirect. The direct method consists in obtaining the urine directly from the ureter or kidney by ureteral catheterization; the indirect, by getting the urine separately in the bladder, or by compressing one of the ureters. This latter method is probably no longer in use.

When it is possible to do a ureteral catheterization the separation is absolute—and this should be the method of choice. True, it is more difficult to do, but it is more certain in its results. Not only is the result of separation more definite, but the source of any pathological products is determined; *i.e.*, whether in the upper or lower urinary tract.

The objections to catheterization are well known, but not well founded. They are (1) that the method is unsafe, (2) that it is difficult of application. My own experience is still too limited to be of great value but in upward of 50 cases in the past eight months there have been no symptoms whatever of any infection, and little or no reaction. Those of larger experience report equally good results. That it is of difficult application cannot be denied, but that it can be done safely is enough to recommend it.

The advantages claimed for the different separators and segregators are, their ease of application and the less danger of infection. It has been my experience that the use of any of the segregators or separators is more painful and annoying to the patient than the cystoscope, especially in the female, for in this class of cases the cystoscope can be removed after the catheters are introduced, and there remains absolutely no discomfort while the urine is secreted.

The worst objection, however, to the use of a separator or segregator is that it furnishes no clue whatsoever as to the source of the pathological elements found in the separate specimens. An ulceration in the bladder may show pus and blood in one specimen and nothing in the other, yet both kidneys be absolutely healthy.

All advocates of these instruments recommend that the cystoscope be used in addition, to diagnosticate the source of the trouble; if, then, the cystoscope must be used to clear up the location of the lesion why not use the catheters at the same time? I use the separator or segregator only when catheterization can not be done, and this occurs in not more than 15 per cent. of the cases.

The obtaining of the separate urines is, however, not the only use for the ureter catheter, but probably the greatest. The additional diagnostic values of the cystoscope and catheter are; (1) whether the bladder or kidney is the seat of the lesion; (2) the presence and location of a stricture of the ureter; (3) the presence and location of a stone in the ureter; (4) a differential diagnosis between diseases of the kidney and surrounding organs, and in this last application I was recently able to clear up two very interesting cases. The one case was a most unusual one, of a male sixty years old, in whom, during the passage of a renal calculus, appendicitis developed; a mass formed over the course of the right ureter in the inguinal region, and by the usual methods

* Read at the Ohio State Medical Society at Dayton, June 3, 1903.

of inspection, palpation, etc., it could not be determined whether we had to deal with an appendiceal abscess or an inflammatory mass around the right ureter. The ureteral catheters were inserted and passed freely; urine flowed with equal rapidity from both sides. A diagnosis of appendiceal abscess was made and verified a few minutes later by opening a large abscess, caused by a necrotic and broken down appendix. The case made a splendid recovery.

In another case of a boy, eighteen years old, who had repeated attacks of right sided pain, chills and fever, muscular rigidity, vomiting, etc., no positive diagnosis could be made. Two physicians had diagnosed appendicitis, one a renal calculus, and still another an inflammation of the gall-bladder. At the time the case was presented for examination a mass could be distinctly outlined in the right hypochondriac region; there was muscular rigidity and great soreness.

From the physical signs present it seemed as though it might be any one of the organs before mentioned. There was, however, a history of having found on several occasions a brick dust sediment in the urine. Double ureter catheterization was done, and a "surgical kidney" on the right side diagnosed. He was operated upon and an infected hydronephrotic kidney removed. A complete recovery followed.

After the urine has been obtained from each kidney, What is the best method for ascertaining the amount of work being carried on by each organ? Albumin in the urine has been the one symptom indicative of a diseased kidney, upon which the profession has relied for many years. No albumin present, has until recently meant no disease. The discovery of casts in the urine, when there was no albumin, changed the significance of the presence of albumin, and caused the profession to seek other means of diagnosis.

The estimation of the total amount of solids in twenty-four hours, especially the amount of urea, has been of great aid in determining the sufficiency of the kidneys, but as this may vary with the quantity of nitrogen taken, upon the amount of exercise, and upon meteorological changes, etc., it becomes a rather unreliable symptom unless all the above conditions are taken into account and the period of examination extended over a number of days.

Slightly less objectionable but not, however, much more satisfactory is the method by which the excretion of certain substances introduced into the body is determined. The first indication of attempting to utilize this method as a diagnostic measure is to be found in the writings of Beauvaire, 1853. He saw in the absence of the odor of asparagus from the urine a characteristic symptom of nephritis. Since then the intolerance of opium, quinine, salicylic acid, mercury, etc., have been held at different times to be an indication of renal insufficiency.

Of late the amount of discoloration of the urine produced by the introduction of methylene blue into the body has gained a more general attention, but recently it has been found that it only tests the permeability of the kidney, and is now more or less abandoned as a diagnostic measure.

Another method which is in part dependent on the secretory function of the kidney, is the so-called phloridzin method, by which not only its secretion but also its chemical activity may be determined. It has been observed when phloridzin was injected into an animal, after a lapse of twenty or thirty minutes, sugar appeared in the urine, the amount varying with the condition of the kidney. It was concluded, therefore, that it not only showed the permeability of the kidney, but also the functional activity of the renal cells.

Casper and Richter have worked this out clinically, and state when combined with ureteral catheterization it is to be classed as one of the valuable aids in the determination of the functions of the kidneys.

Besides the various chemical methods just mentioned there remains another method, which is probably destined to play a greater part in the diagnosis of the renal function than any other that has yet been introduced. This method is cryoscopy. To this procedure I desire particularly to call attention. As is well known, the greater the number of molecules in a given solution the lower will be the freezing point below that of distilled water, and in this way the amount of solid constituents in the urine and blood can thereby be obtained.

Dresser was the first to apply this to urine, but it was Koranyi who first gave this method its practical application in demonstrating thereby the secretory activity of the kidney. This work of Koranyi created a very great interest among the scientific clinicians, and much has been done and written on this subject. While none attribute to it absolute worth, all agree it is of the greatest supplementary aid. The normal freezing point of the urine varies from 1 to 2.3 below that of distilled water. The normal freezing point of the blood being .56 to .57.

Kümmel has made a study of the freezing point of the blood in 265 persons including 137 subjects with normal renal functions. If the freezing point remains within normal limits, .55 to .57, in a case of unilateral nephritis, the kidney can be removed without apprehension; that is to say, the other kidney is doing compensatory work. In 40 such cases recovery was uneventful and the renal function undisturbed, while in every case in which the freezing point was .59 exhibited a sluggish renal function afterward and also albuminuria.

These facts are further established by the results in the cases in which the freezing point was .58 to .81. The assumed renal insufficiency was confirmed in every instance by the autopsy or operation. Nephrectomy is still possible at .50, but .60 is the extreme limit of permissible nephrectomy. It has been found in nearly all the cases when the freezing point of the blood is low, that of the urine will be high. Urinocryoscopy with ureteral catheterization and urine separation has

been of the very greatest aid in my clinical experience.

The freezing of the urine is a comparatively simple matter. At least sufficient urine to cover the bulb of the thermometer should be used. The Beckmann apparatus is probably the best instrument. The freezing should be done while the urine is fresh.

In two cases of tuberculous pyonephrosis, in one case of a suppurating cyst of the kidney, in one of pyelitis and infected hydronephrosis, and in one of miliary tuberculosis, the functionating capacity of the supposed healthy kidney was ascertained by urinocryoscopy. All of these cases showed a renal sufficiency. Nephrectomy was done in each case, and all made good recoveries. An equally good result was obtained in a case of nephrotomy.

In two cases, one of hematuria and one of pyuria, operation was advised against because of renal insufficiency. The justification of this advice was demonstrated when both cases succumbed to uremia, one ten days and the other three weeks after the examination.

In a number of cases pus has been demonstrated in one or the other kidney, but in all of these cases a good functionating capacity was present. The kidney substance was probably not much involved, the infection being mostly in the pelvis of the kidney. In such cases the administration of urinary antiseptics and irrigation of the pelvis has been of very great benefit.

The writer does not offer this method of cryoscopy as a substitute for the other methods of examination, for it in no way determines the anatomical condition as shown by the presence of pus, casts, red corpuscles, and micro-organisms, but offers it only as an important supplement, and as the best known way at present of determining the functions of the kidney.

The deductions from a previous paper on the same subject are submitted in conclusion:

1. Before doing a cutting operation upon a kidney—especially before doing a nephrectomy—the presence of a second functionating kidney should be established.

2. The best and safest method for ascertaining the presence of a kidney is by the aid of cystoscopy and ureteral catheterization.

3. The function of the kidney is best determined, in order of importance: (*a*) By the freezing point of the urine; (*b*) by phloridzin glycosuria; (*c*) by the quantity of urine excreted; (*d*) by the freezing of the blood.

4. The most reliable method of obtaining the separate urines is by the ureteral catheter.

Colorado Medicine.—The Colorado State Medical Society has decided to publish a monthly journal. This will include its Transactions, replacing the annual volume. But it will perform a more important function, as the official organ of the State Society and the component County Medical Societies. It will publish official announcements of these societies and furnish a general means of communication between their officers, committees and members. We wish it success.

SOME EXPERIMENTS AND CONCLUSIONS IN HYPNOTIC THERAPEUTICS.*

BY W. H. WALLACE, M.D.,
OF DISPUTANTA, VA.

My attention was first called to hypnotism in a medical way in 1898. In the summer of that year I met a lady who assured me she was a natural born "magnetic healer." She affirmed that by a few strokes of her hand she could put her husband (who was an invalid) into a sound sleep. He was subject to various neurotic pains, which she could always control by stroking. Numbers of her friends assured me they could feel a pecular thrill when she touched them. I had never heard hypnotism mentioned in my medical course, and had always considered it a humbug, but here were a number of reliable people whose word was not to be questioned, who assured me they could feel *something* pass from this lady's hand to their own. What was it? Animal magnetism, as she asserted? or hypnotic suggestion? It was two years later that I began some experiments on my own account. My wife was affected with pains along the course of the sciatic nerve, and one night I said carelessly, "Oh, I can stop that in two minutes." I massaged both nerves lightly and told her her pain was gone; she moved them and felt no pain. She was not nearly so much surprised as I was. From this I concluded that hypnotism was not all humbug, so I purchased a set of good books on the subject and went to work to investigate more thoroughly. I have been thus prolix, to show that it was no hypnotic grand-stand play that brought me to a study of the subject, and that, at the beginning, I was anything but prepossessed in its favor.

Following instructions of Yerkes, of Harvard, I could readily hypnotize hens and discovered that some were more easily influenced than others. I met a young lady who told me she had been hypnotized several times, and I had no difficulty in putting her in the rigid, so-called cataleptic state.

After this I began to use my newly-acquired accomplishment freely as a means of relieving pain in all suitable cases, such as neurotic headaches, insomnia, and all kinds of obscure functional nervous troubles, and as an aid to hasten the effects of chloroform in anesthesia. I was successful in stopping night-sweats of phthisis, and put a patient (who had an idiosyncrasy for morphine) to sleep in the agonizing crisis of locomotor ataxia.

I wish now to call attention to a few, to me, remarkable cases before attempting to draw conclusions:

Case I.—Mrs. G., aged fifty-three years, married, no children; had been an invalid for twenty years when first coming under my care, and had all the clinical symptoms of phthisis and a bountiful supply of the *Bacillus tuberculosis* in her sputum. She was very weak; had precordial pains and could not sleep. I had exhausted the pharmacopœia in endeavoring to give her rest. It occurred

* Read before the Thirty-fourth Annual Session of the Medical Society of Virginia.

to me one evening that this would be a heroic test case for hypnotism. I put her in a comfortable position, and in ten minutes I had her sleeping soundly and she slept all night. As long as she lived I could make her comfortable by a few strokes of my hand and a few firm words of suggestion or command. Her husband suffers from locomotor ataxia, and has an idiosyncrasy for morphine, which crazes him. I had run the gamut of anodynes in his case when the crisis was on and had given him very little relief. In his case I used a revolving mirror, fixing the light behind him and getting the mirror in such position that it would flash the rays of light in his eyes. He was in such pain that his cries could be heard a block away. To quiet his craving for something to take I gave him five grains of bromide, and fixed his attention on the mirror, explaining to him that the rays of light would paralyze the ocular nerves, etc., and he would soon fall asleep and be free from pain. Difficult as he was to control, in fifteen minutes he was sound asleep, and he slept for two hours. I then put him to sleep again, and he slept all night without rousing. In the room with this patient was a half-grown puppy, and the colored nurse called my attention to him just as I had got my patient asleep. The puppy had been attracted by the bright revolving mirror, and when I looked at him he was blinking and unsteady on his legs, and in a couple of minutes fell over against the hot stove, which awoke him.

Case II.—The next case I wish to speak of was a stout woman, aged sixty-two years. She suffers with valvular trouble, and has asthmatic attacks at times. She became frightened and precipitated an attack one day while I was away. When I saw her, some three hours later, she had the most irregular pulse I ever felt, and had an abiding fear that her end was near. I got her to bed, and with a few quiet strokes over the temples and appropriate suggestions she went to sleep, and now, after some nine months, she has not had a recurrence.

Case III.—My next case worthy of mention was one of delirium tremens. Mr. M., a married man and a farmer; had at one time been a pillar of the Church, but, like many pillars, had fallen. When in his cups, that seemed his chief grief. When I went to see him, he was in a particularly bad fix, his horses were running away with him and deacons were putting him out of church. He would not take medicine nor allow me to use a hypodermic, and he was too powerful a man to think of using force with, so I decided to try hypnotism. It was out of the question to try ordinary methods, because I could not hold his attention; so assuming a tragic air, I shouted to him, "Don't you see the water around your feet, they are trying to drown you, get to bed, quick!" He took the suggestion readily, and seemed in abject terror of the water. I was then able to control him, and in half or three-quarters of an hour had him asleep. I went home hoping to hold him till morning, but he awoke in two hours, though more rational, and in a couple of days was over his attack. He had another spell six months later, however, and committed suicide.

Case IV.—A Bohemian young man came to me from Pennsylvania with some obscure nervous trouble. He had been to see several specalists and was growing progressively worse. He had vague pains in calves of legs and thighs, weak back; was unable to work and had constant headache and roaring in his ears. Strange to say, none had thought to examine his ears; and I had been treating him for two weeks before it occurred to me to look for impacted cerumen. Both auditory canals were packed full, and how he could hear so well with them in that condition is a mystery to me. I syringed them out, and thought I had solved the riddle of his case, but in a few days he began to grow worse. I had his eyes examined and his vision was 20—20, no trouble there. I had been using electricity, superheated hot air to spine and cold douches. As a last resort, I tried hypnotism and in ten days I had him out in the field at work. Of course, I gave him tonics in conjunction with the other treatment; but the fact remains, that he did not commence to mend till I had hypnotized him several times.

I have thus briefly run over these cases to show effects, or, better, results. I will now try to draw some conclusions. I am not quite prepared at this time to follow the latest teaching as to the action of, or cause of hypnotic sleep. Nearly all modern writers claim that suggestion is all there is to it. I cannot believe this; I have hypnotized chickens by holding their feet, laying them on a board and putting a grain of corn in front of their beak. I can see no suggestion in this. As I have stated before, I involuntarily put a puppy to sleep with a revolving mirror. To my mind, the whole keynote of the phenomena is concentration; suggestion only helping to hold the mind or concentrating it.

It would not surprise me at all to find the students of the science (if I may so call it), at some later date go back to the teaching of Mesmer, and show that there is a psychical force that produces the phenomena we call hypnotic sleep.

I do claim, however, (and believe that further research will bear me out), that hypnotism has a definite physiological action, as much so as any drug of the pharmacopœia. So far as I have been able to find out no one has ever advanced this theory, and thereby hangs the secret of much of the neglect of one of the most powerful weapons in the armamentarium of the physician. I do not claim that it is a cure-all. I do not even believe that every physician is capable of exercising it successfully, but to a large body of the profession it is a wonder-worker in a great many cases. Up to this time, as I have said, it has been used empirically and mostly by quacks and advertisers; but because a quack uses a thing that is good it is no reason that we of the regular profession should ignore it, and if we can show that its effects are at all times the same or nearly the same—that all patients submitted to its action behave the same, I think we are justified in claiming that it has

a definite physiological action. I believe that its action is simply this: attention is concentrated on, or by something to such a degree that strain is put on the vasomotor nerves, resulting in a paresis of the whole vasomotor system, with a consequent diminished blood pressure. A patient subjected to hypnotic suggestion invariably (in my experience) starts off with a rapid small pulse, a little later it gets harder slower and full, and as hypnosis comes on tension diminishes, and if you put one of them into deep somnambulism, the pulse is flaccid and slow. As I said before, blood pressure is diminished, what results? Blood is very easily determined to any portion of the body, because the vessels are wide open, with but one exception. I believe that whereas in physiological sleep the brain is anemic, in hypnotic sleep it is congested, for though the body is asleep the brain is still active and blood is bound to circulate more freely where there is most activity. Now, then? I concentrate a patient's attention on a rapidly revolving mirror, and suggest to him sleep. I say you are bound to sleep if you keep your gaze on it. He concentrates his attention on it, all else is blotted out, his whole attention is on that mirror, and sleep dominates him; blood is pouring into the brain, where activity alone is going on; surroundings get hazy and he does not notice anything but that dominant suggestion, sleep, and as a result he is soon asleep. Well, what happens then? We will suppose he is a man who has been troubled with a mild neuritis of the leg and foot. He is sleeping soundly, with a brain turgid with blood. I say to him, "You feel no pain in your leg or foot." His attention is now directed to that foot, there is a rush of blood to the particular brain center that presides over that limb, the brain cells of that center are crowded together and massaged against one another by the flowing blood, gradually nutrition there (because of increased metabolism) is increased.

The center that appreciated pain no longer appreciates it, not by any wonderful psychical process, but by a simple reasonable physiological process. Well, some one says, "You have not removed the source of irritation; when the patient wakes the pain will return, you have not increased metabolism in the limb." I am not too sure of that. True, if there is any material organic change of the tissues that is causing the irritation, it may not be possible to cure it except by extended treatment, and perhaps not then; but at the time you draw the patient's attention to the painful area metabolism increases in that part as much so as in the center presiding over it. Tissue changes take place, the parts are flushed out because of diminished tone of blood-vessels, and the minute vessels are capable of taking up larger extraneous particles than they would at any other time; and they are so taken up and swept out of the tissues and into the general circulation and on out of the system.

To recapitulate then, my idea is that the phenomenon of hypnotism in its action on the human economy is a definite physiological process. It has its psychic side to be sure, but I do not care to discuss that at this time. I believe that it cures pain and many functional troubles by a process as easily understood as is the physiological action of—say digitalis or opium. I know that some of my deductions are not capable of proof, but how many things in medicine are? I have carried on my studies and experiments during the exigencies of an extensive country practice, and this thesis is far from what I would have desired. But if it will help to stimulate research in this field by some better prepared and more fortunately situated than myself, and if I have succeeded in demonstrating that hypnotism is a therapeutic agent too good to be left to charlatans, my labor will not have been in vain.

MEDICAL PROGRESS.

MEDICINE.

The Overlaying of Infants.—England exceeds all other countries in the proportion of deaths of infants under one year of age from suffocation in bed with their parents or nurses. William W. Westcott (Brit. Med. Jour., Nov. 7, 1903), coroner for N. E. London, reports that during the recent ten years there were 15,009 overlain infants in England and Wales. In Liverpool, during one year, there were 143 cases out of 160 inquests. In London the death rate from this cause is shamefully high, although probably the records show a somewhat lower rate than is actually the case, on account of the difficulty of diagnosing the conditions. The factors aiding and establishing this diagnosis are skin discolorations, pressure marks, the most important of which is flattened nose. In addition to this there are often present the well known signs of suffocation. It is probable that if a drunken mother should nurse her infant before going to sleep, the baby may be more or less stupefied by the alcohol in the milk, and so fall a prey to easy suffocation. These cases very naturally are not apt to give the grosser signs, because they may succumb to the simple pressure of the bedclothes. The English law allows parents to take infants to bed with them. It probably gives opportunity for a vast number of infanticides. Under the old penal code of Prussia, mothers were forbidden, under pain of imprisonment, to have children under two years of age sleep in bed with them. In Westphalia, and, indeed, throughout France and Germany, this form of infantile death is almost unknown. This happy condition probably arises because in that section of the continent the drunken mother is unknown. In London, Liverpool and Glasgow, however, she is a frightfully common sight. In the present condition of the English laws it is not possible to secure conviction of parents for the manslaughter of infants by overlaying, and the appalling frequency of the condition would seem to justify the enactment of suitable preventive laws.

Results of Organotherapy in Addison's Disease.—Cases of Addison's disease are so uncommon that it seldom occurs that any one physician sees a sufficient number of these patients to make his conclusions in regard to the value of treatment of any avail. E. W. Adams (The Practitioner, Oct., 1903) has collected 97 cases from the English, French and German literature, all of which have been treated for a time at least with some form of extract from the suprarenal gland. Many of these were treated but a short time, and some of them were practically moribund when the treatment

was begun. Furthermore, it was, of course, impossible to be certain of the diagnosis in all cases on account of the numerous sources from which they were taken, and also because the diagnosis is frequently a very difficult matter even to the most skilled. Autopsy records of a considerable number were also obtained to confirm the diagnosis whenever possible. The results show that 7 cases were made distinctly worse by treatment; 43 cases derived no real benefit; 31 cases showed marked improvement, and 16 were apparently permanently cured. The best results were obtained by the use of the first gland, given by mouth, and the fluid or solid extract given in the same way. Three cases of suprarenal grafts were all apparently made worse by the operation. It would appear, therefore, that there is a certain class of cases of Addison's disease which derives indubitable benefit from the exhibition of some form of suprarenal substance, though in any given case it still remains impossible to determine its probable response to the treatment. Although the chances of recovery are comparatively slight they are certainly much better with this mode of treatment than with any other.

General Views on the Etiology of Infectious Diseases.—In the first of the series of Harben lectures delivered in King's College, London, F. Hueppe (Jour. of State Medicine, Nov., 1903) treats of the general causes of infectious diseases. In addition to the two opposed views—namely, the one supported by Pasteur and Koch, that an "animated contagium" is the external cause of a specific infective disease, and the other, that the "diseased cell" is the entity of the disease, as enunciated by Virchow, there still exists a third opinion. It is recognized by Simon, Farr and Parkes in England, and Pettenkofer in Germany, that external conditions are of great importance in the propagation of infectious disease. The author was the first to try to bring these three theories into harmony with one another, and demonstrated that for an infectious disease to break out, the cells of the body, the pathogenic microbes and the external conditions must be in energetical or dynamical relations with one another. The author believes that individual "predisposition" rather than a predisposition of the species or race, as maintained by Baumgarten, is a fact, and must be accepted by all naturalists. Rather than predisposition being a negative fact—negative, from the absence of immunity—it is something positive, and a "correlate" to the immunity. Predisposition of the protoplasm corresponds to the constitution of the molecules in chemistry. Protoplasm, as active molecule, cannot be recognized by the analytic and synthetic methods of chemistry, but it can be recognized by the biological method—by means of the reaction to a "stimulus." The latest physical theory of the action of the enzymes teaches that the stimulus, as enzyme, can produce an effect if it has corresponding groups in the living molecule. This also applies to the meaning of the specificity of the pathogenic bacteria as stimuli. "Physiological assimilatory stimulus agrees with the specific cell protoplasm as a good key fits a lock, whereas pathogenic bacteria agree with the same specific protoplasm as a false or skeleton key fits a lock, which lock becomes either destroyed or opened." Infection and immunization is the biological method of recognizing the predisposition which cannot be demonstrated directly. The predisposition of the child is different from that of the adult. Moreover, besides his inherited nature, man also has a "second nature," dependent on the normal evolution and on the influences of environment and internal causes. Thus, cold, heat, damp, hunger, thirst, mechanical injuries, alcoholism, or other forms of intoxication, constitutional illnesses (as diabetes or rickets) can augment the predisposition to infectious disease. Pathogenic bacteria have no unvarying specific character; *e.g.*, bacteria of diphtheria, pneumonia, etc., have often been found in the bodies of healthy men; the same specific bacteria do not affect all animals alike with the same typical disease, diphtheria bacilli may cause local diphtheria, or acute blood-poisoning or paralysis; similar symptoms can be evoked by entirely different germs, which can also produce identical anatomical changes. Illness is a function of changeable predisposition, changeable stimulus, and changeable external condition. Each one of these factors can vary from minus to plus, from nought to infinity. If one mark illness "I," predisposition "P," stimulus "S," and condition "C," one has, as a general expression, $I=f$ (PSC). If the conditions are constant or without special value, then $I=f$ (PS). Every one of these factors can be composed of several factors, as, for instance, the predisposition "P" can be inherited (p) and acquired (p'); then $I=f$ (p+p', SC). Recognizing disease as a function and being able to express the different factors mathematically as curves, pathology acquires a certain degree of exactitude. The different methods of hygiene as statistics, post-mortem examinations, chemical researches, physical and biological experiments must all work together in order to recognize the different single factors.

Caisson Illness and Diver's Palsy, an Experimental Study.—The following conclusions were derived by L. Hill and J. J. R. Macleod (Jour. of Hygiene, Oct., 1903), from the experimental investigation of this subject: Compressed air above 5 atm. lessens the CO_2 output, and lowers the body temperature in mice, rats and young rabbits. Oxygen at and above 1 atm. has the same effect. It is a sign of oxygen poisoning. Compressed air at 10 atm. is more damaging—at least to small animals—than oxygen at 2 atm. Compressed air increases the loss of body heat both because it is a better conductor and because it is saturated with moisture. The saturation of the air with moisture in caissons does not prevent evaporation from the body, because the skin temperature is above that of the air. The wet air by damping fur or clothes increases loss of heat. Highly compressed air may possibly interfere with the diffusion of CO_2 from the alveolar air, and may, owing to increased friction, hinder the passage of air in and out of the air-tubes. The nitrogen output in dogs is not altered in any noteworthy degree by exposure for six hours to 8 atm. air. Inflammation and consolidation of the lungs are produced by exposure to 8 atm. air for over twenty-four hours. One and a half atm. of pure oxygen has a similar effect. The higher the oxygen tension the more rapidly does the inflammation ensue, *e.g.*, 6 atm. O_2 produces marked congestion in two hours. It does not seem likely that inflammation of the lungs should be produced in the pressures and times of exposure usual in caissons. Excised frog's hearts, muscles and nerves are not rapidly poisoned by even 50 atm. O_2. A heart will beat more than an hour exposed to this pressure. The vagus nerve endings appear to be paralyzed by such exposure, while inhibition can be obtained by stimulating the crescent. All animals investigated, vertebrates and invertebrates, are instantly convulsed and killed by exposure to 50 atm. O_2 convulsions are frequently produced in vertebrates by exposure to 4—5 atm. O_2, while exposures to 6—25 atm. O_2 produces dyspnea and coma, and the convulsive stage does not usually appear. Cleaning movements, salivation, gaping, jerky, deep respiration, are symptoms which precede the convulsions, and coma soon follows them. With air pressures up to 12 atm., convulsions are not observed. Salivation, dyspnea and coma are the symptoms. The blood gases increase in compressed air or oxygen according to Dalton's law, but

the process of complete saturation of blood and tissues takes some time. The circulation is unaffected mechanically by compressed air. The cause of caisson-sickness is the escape of gas bubbles in the blood-vessels and tissue fluids on decompression (release of compression). An animal exposed for four hours to 8 atm. air and quickly decompressed is like an opened bottle of soda water. The fluids of the body generally effervesce. The effervescence can be studied in the circulation of the frog's web or bat's wing, the animals being enclosed in a suitable chamber. It takes a little time for the bubbles to grow to an appreciable size. Recompression causes the bubbles to go into solution, and if applied quickly enough the circulation recommences. The bubbles after rapid decompression can be seen post mortem in the blood-vessels, in the heart, retinæ, aqueous humor, connective tissue spaces, etc. The alimentary canal is blown out with gas. The bubbles produce cyst-like cavities in solid organs, *e.g.*, in the central nervous system, the liver. The cells are compressed round these cysts. In the case of oxygen, an animal may recover after an extraordinary amount of this gas has been set free by decompression. The nerve cells are not killed by the oxygen bubbles, and the animals are convulsed and exhibit hyper-reflex-excitability. The varying symptoms of caisson-sickness are due to the varying seat of the air-emboli. Young men escape the disease owing to the elasticity of their tissues and greater facility of collateral pathways of circulation. By the choice of suitable men, and proper regulation of the period of compression and decompression, caisson and diver's sickness can be avoided.

Granuloma of the Nose, Due to Iodide of Potassium.—A case of specific disease of the nose and larynx and a granuloma on the tip of the nose, is reported by C. P. Crouch (Bristol Med.-Chir. Journal, Sept., 1903). The chief point noted about this rare condition is that its nature is apt to be overlooked, and consequently the iodide to be continued. In this case the diagnosis was rendered more difficult by the fact that some undoubted iodide spots on the forehead disappeared, while the granuloma increased. Acne due to iodide is apt to become tuberous. Iodide rashes are more apt to occur if there be either cardiac or renal disease present, causing a defect in elimination. An iodide rash may begin in twenty-four hours in pot. iod., gr. v t.i.d. The case reported is also of interest, inasmuch as the patient attributed his condition to "grease" from which a horse under his care was suffering.

Lime Dust in Pulmonary Tuberculosis.—In order to determine the practical value of inhalations of lime dust in pulmonary tuberculosis, a series of tests have been made by P. Reckzeh (Berl. klin. Woch., Nov. 9, 1903) in eight patients which presented various degrees of involvement from slight apical lesions to extensive double cavity formations. It has been asserted that workers in factories where lime in the form of dust was present, were markedly benefited if they were afflicted with tuberculosis. The patients on whom the tests were made were subjected to daily inhalations of finely powdered, freshly calcined lime, for periods of five minutes or longer. The results obtained were not encouraging as the objectionable features far outweighed any possible benefits. Chief among these were the increased irritant cough, nausea and sometimes vomiting, loss of appetite, a feeling of lassitude, burning pains in the chest and severe headaches. No objective changes in the pulmonary lesions could be detected.

Value of Sanitarium Treatment in Tuberculosis.—The permanency of the beneficial effects of this method of treatment have been made the subject of a research by L. Brown (Jour. Am. Med. Assoc., Nov. 21, 1903). He has made an analysis of fifteen hundred cases discharged from the Adirondack Cottage Sanitarium from two to eighteen years ago and adheres to the classification of the types of the disease proposed by Trudeau. In all, 33 per cent. of cases are alive, 38 per cent. are dead, and 29 per cent. are untraced. Of those alive, 22 per cent. are well, 4.6 per cent. are arrested, 3 per cent. relapsed and 3.7 per cent. are chronic. Taking all the cases traced (1,066) together, 31 per cent. are well, 6.5 per cent. are arrested, 4 per cent. have relapsed, 5.2 per cent. are chronic and 53.3 per cent. are dead. Of the incipient cases 66 per cent. are well and 21 per cent. are dead. Of the advanced cases, 28 per cent. are well and 52 per cent. are dead; while of the far advanced cases 2 per cent. are well and 90 per cent. are dead. No doubt, however, more of the untraced cases are dead than these figures would indicate. In 10 cases it is known that death was due to other causes than tuberculosis.

A New Method for Diagnosing Typhoid.—The clinical value of the Gruber-Widal serum reaction is more or less restricted by the necessity for laboratory facilities and the time required in getting results. In order to make the Widal test more practical, the following conditions, according to M. Ficker (Berl. klin. Woch., Nov. 9, 1903), must be fulfilled: (1) the place of the living cultures of typhoid bacilli must be filled by a substitute as the physician in general practice usually does not possess the former; (2) the preparation must contain the specific agglutinating properties and possess keeping qualities; (3) the reaction must be visible to the naked eye, must always result uniformly and not require any extended period for its observation, and (4) must be possible at ordinary room temperatures without the use of an incubator. The author believes that he has devised a method which fulfills these requirements. The test fluid and its action are described but the method of preparation is not indicated. It is a slightly cloudy, sterile fluid, which when kept dark and in a cool place, has remained effective for nine months. The serum to be tested is diluted ten times with normal salt solution. Of this 0.2 c.cm. are placed in one test-tube and 0.1 c.cm. in another. To the first is added 0.8 c.cm. and to the second 0.9 c.cm. of the diagnostic fluid. In a third test-tube is placed 1 c.cm. of fluid without the addition of any serum. The test-tubes are then stoppered, thoroughly shaken and set aside in a cool dark place for from ten to fourteen hours. When held against a dark background, the positive reaction is indicated by a clearing of the fluid, while the agglutinating materials have sunk to the bottom of the tube. The results attained have corresponded exactly with those secured with previous methods and in judging the presence or absence of typhoid fever, the same precautions must be observed. He claims that the method has been successfully used in several large German clinics. The preparation is at present made by Merck of Darmstadt.

Recent Literature on Diphtheria.—A review of the publications upon the subject of diphtheria during the past year reveals several interesting questions, for the solution of which considerable evidence is offered. C. B. Ker (Practitioner, Oct., 1903) quotes freely from a paper by Martan who believes that there is much less discrepancy between clinical and bacteriological results than is sometimes asserted and that this discrepancy is often due to errors on the part of the bacteriologist or physician. He holds that the diagnosis can be made clinically with a probability which amounts to almost

certainty and at least with sufficient accuracy to determine whether antitoxine is indicated or not. He does not appear to believe in a simple catarrhal diphtheria and when no membrane is present the question of diphtheria may be dropped. The relationship of true diphtheria to follicular tonsillitis is an interesting point and Marfan believes that certain true cases, especially when the larynx is involved first, do present the appearance of tonsillitis. In his wards 80 per cent. of the cases of follicular tonsillitis accompanied by laryngitis were diphtheritic, whereas under one-half per cent. of follicular cases with no laryngeal symptoms were found to be diphtheritic. Some of the causes of death are carefully studied by Babier and he urges the importance of cardiac thrombosis and tuberculosis. In 69 autopsies he found ante-mortem thrombi present in the heart in 37 or 52 per cent. In 19 cases in which bacteriological examinations were made the diphtheria bacillus was found in the clots in 18 instances. The patients usually die suddenly during convalescence. He also believes from numerous autopsy findings that diphtheria lights up old tuberculous processes. Perhaps the most useful contribution upon the subject of treatment is the suggestion by Cairns who has used the antitoxine by intravenous injection in the severe laryngeal and nasal forms. He recommends large doses, 20,000 to 30,000 units, in order that the large doses of toxine which have evidently overcome the system may be neutralized. If given subcutaneously the lymphatic glands seem to prevent the serum being absorbed rapidly enough to prove successful. The cases of bronchopneumonia complicating diphtheria are now recognized as being usually due to the Klebs-Löffler bacillus and the rapid absorption of toxin in these cases also can perhaps best be withstood by large intravenous injections.

A Classification of Leucemia.—It is now generally believed that all forms of leucemia must be looked upon as a hyperplastic tumor-formation in those organs which produce leucocytes. A lymphatic leucemia results where the cells without granules are chiefly involved and a myelogenous and lieno-myelogenous type where the granulated cells chiefly proliferate. The last class generally develops more slowly; in fact most cases of acute leucemia are lymphatic. It is probable that the cells of the lymph-nodes and spleen may become granulated so that theoretically participation of the bone-marrow is not absolutely necessary in the myelogenous form, though practically it almost always occurs. To properly understand the pathology of blood-diseases, F. P. Weber (Virchow's Archiv, Vol 174, No. 2) finds it convenient to divide them into the following classes: (*a*) Proliferation of lymphocytes in the bone-marrow, without migration of the cells into the circulating blood: Myelogenous pseudoleucemia, myelogenous lymphosarcoma, lymphadenomatosis ossium and multiple myeloma of lymphatic type; (*b*) like above, but with passing of the cells into the blood: myelogenous lymphocythemia, including some cases of acute lymphatic leucemia; (*c*) new formation of lymphocytic cells in the lymph-nodes and lymph-adenoid tissues in general, without migration into the blood: lymphatic or splenic lymphadenoma or pseudoleucemia. The chronic cases are characterized by the presence of more fibrous tissue. (*d*) Like above, but the cells enter the blood: lymphatic or splenic lymphocythemia. (*e*) Proliferation of cells on the type of medullary myelocytes, without migration: myelogenous pseudoleucemia. Some cases of multiple myeloma also belong here. This class is characterized by the presence of Bence-Jones' albumosuria. (*f*) Like above, with abundant cells in the blood: myelogenous or spleno-myelogenous leucemia. Occasionally the character of a leucemia changes from myelogenous to lymphatic without involvement of the lymph-nodes; in such cases the process has become more acute so that the medullary cells have not had time to develop granules. Why in one case the cells leave the organs, and in the other not, is not known but possibly the cells in the latter class have lost their power to wander or to continue their existence in the blood.

Relation of Leucemia to Tuberculosis.—A few cases have recently been reported in which these two diseases coexisted, but considering the frequency of tuberculosis the association of the two diseases is important more on account of its rarity than its frequency. W. J. Sussmann (Practitioner, Oct., 1903) was able to collect twenty-five instances in which there was little or no doubt of the presence of both diseases and he is able to show that it was usually the lymphatic form of leucemia which appeared, although, in general, the splenomedullary form is the more common. An interesting point upon which he dwells is that the two diseases probably exert an antagonistic influence over each other. The most striking difference between the two diseases is the presence of a marked mononuclear leucocytosis in leucemia and an absence of leucocytosis in tuberculosis. This leucocytosis must be inimical to tuberculosis by increasing the amount of nucleo-albumin present in the body and by increasing the phagocytic action of the blood. The myelocytes possess this latter characteristic to a greater degree than either of the other kinds of leucocytes and this is offered as a reason why splenomedullary leucemia is even much more rarely associated with tuberculosis than lymphatic leucemia is. This theory of the power of nucleo-albumins to inhibit the growth of tubercle bacilli has been made use of by the employment of nitrogen and nitrogenous products as the remedies *par excellence* for the tubercle bacilli. Urea has thus been used. The ferment-treatment has also been introduced, being administered as pure yeast. Pure yeast-cells are distinguished by the large amount of phosphorus which they contain and the nucleins, obtained from yeast cells, differ very little from those of animal cells. In leucemia this excess of nucleins is already present.

Diseases Simulating Typhoid Fever.—Many authors described various diseases which simulated typhoid very closely, and the meaningless term of paratyphus was proposed by some as a designation for this class of affections. D. D. Pletneff (Roussky Vrach, Oct. 18, 1903) reports two cases in which typhoid had to be excluded only by a bacteriological examination as clinically there were typical symptoms of the disease; an incubation period, fever of a remittent character and always high, enlarged spleen, prominent nervous symptoms and diarrhea. In neither of the cases could the Gruber-Widal reaction be obtained. The secretions contained the colon bacillus.

Endothelioma of the Pleura.—Endothelial cancer of the pleura has been described by many authors under various names such as pleuritis carcinosa, lymphangitis carcinomatodes, lymphangitis prolifera, etc. It was considered as an inflammatory process because the swelling took its growth principally from the local elements, whether found primarily or after it had generalized, and also because of its diffused character as well as the various clinical symptoms pointing distinctly to inflammation, which in its final stages brought about tissue alterations that produced the picture of a cancer. According to A. I. Bourtzeva (Roussky Vrach, Oct. 18, 25, 1903) all authors agree that it is the endothelial cells of the lymphatic vessels that give rise to the formation of the endothelial tumors of the pleura. The case which forms the basis of the author's investigation was that

of a man of forty-one years who was admitted to the hospital complaining of difficulty of breathing, cough and general debility. The dyspnea began about three years ago, and kept constantly increasing. He underwent evacuation of the pleural cavity three times during this period, but experienced only temporary relief therefrom. He presented marked cyanosis; the left side of the chest was considerably enlarged, the intercostal spaces smooth. Percussion elicited perfect dulness over both apices on either sides, the dulness also extending downward. The respiratory murmur was absent in a great part of either lung. The expectoration contained many bacteria, principally staphylococci; no tubercle bacilli. The pleura was tapped and 1,350 c.cm. of an opalescent fluid was extracted. Relief was obtained which lasted but a few days, the patient's condition grew gradually worse, and he finally died of what seemed to be paralysis of the heart. The autopsy showed the patient to have suffered from an endothelioma of the pleura, which owed its origin not only to the endothelial cells of the lymphatic vessels and spaces but also to the perithelium of the blood-vessels. The growth had also invaded the upper lobe of the adjacent lung, and some portions of the mediastinum.

Primary Malignant Intrathoracic Tumors. The clinical manifestations may be divided into those of centripetal and those of centrifugal extension, according to T. N. KELYNACK (Med. Press and Circ., Nov. 4, 1903). The general evidences of these growths when their development is rapid, may be marked. The distinct cancerous cachexia is, however, not usually pronounced. Clubbing of the finger ends is occasionally a prominent factor. Under certain conditions of extremely rapid growth, however, a carcinoma may run a course very similar to that of acute lobar pneumonia. Dyspnea occurs usually very early and may be the only symptom. It may be persistent, or paroxysmal; it may or may not be varied by posture and may be inspiratory or expiratory; it may be perceptible only upon exertion. Orthopnea develops in a large part of the cases. Cough due to pressure is a very early symptom. It is apt to be very characteristic and may accompany alterations of voice. Hemoptysis, when present, is an important symptom. The sputa examination, however, does not usually give any help. Cyanosis is often marked. The nervous derangements due to the involvement of the sympathetic central nerve symptoms by pressure are manifold. Prominent among these is the contraction of the pupil, which may be accompanied by ptosis. Occasionally the brachial plexus may be involved. The lesion must be differentiated from abscess and syphilis, from bronchitis from peraphetic and pericardiac conditions and from aneurism.

Radium in Medicine Hardly has the medical profession recovered from its surprise at the wonderful results obtained by the application of X-rays to medicine when another even more potent remedy is placed before us by the discovery of radium. The beneficial results to be expected from X rays, together with the limitations of its use, are now being thoroughly worked out and recognized by its extended and varied application to numerous pathological conditions. Although the phenomenal results at first hoped for the X-rays have not been entirely realized, yet this agent has fully proven its claim as a useful and potent remedy in the treatment of many diseased conditions. The price of this new substance, $2,700,000 a pound, prevents its very extended use in medicine at the present time, but the price will undoubtedly be diminished when better methods of separation have been found. Its wonderful activity in emanating heat and light rays is not accompanied by any discoverable loss of weight or diminution in energy and hence the principle of the conservation of energy seems to have met a stumbling block when applied to the properties of this metal. S. G. TRACY (N. Y. Med. Jour., Oct. 24, 1903) shows how active radium is when brought in contact with living cells and germs. A small piece carried in the pocket for a few hours will cause a severe burn resembling closely that from prolonged exposure to the X-rays. It is powerful in killing cultures of bacteria, even when exposed for a short time. Radium salts when brought near to the temples or closed eyes cause sensations of light. Patients blind for years have been made to see slightly. Very good results have been reported from the use of the salts of radium in cases of rodent ulcer, superficial cancer, various kinds of skin disease and optic atrophy. In the treatment of tuberculosis of the lungs Soddy suggests that radium be dissolved in water. He says "that instantly all its emanations are evolved in gas and mixed with the air above the solution. These emanations can be stored in a gas holder and one-half the emanations will disappear every four days till at the end of three weeks all will be gone. The solution containing the radium will be found to be just as active as at the beginning and seems to have regained its potency during the three weeks." Inhalations of these emanations leave a thin film of radioactive substance in the lungs which exerts a germicidal power over diseased tissue long after the emanations have been exhaled. Experience has not yet taught us how much to expect from this method of treatment.

Diet of Bread and Fruit and Its Effects Upon High Blood-pressure, Dropsy and Obesity.—It has been found that a healthy person weighing about 140 pounds will require to eat 28 ounces of foodstuffs a day and of this 21 ounces may be taken as breadstuffs and 7 ounces as dried fruits. A. HAIG (Med. Rec., Oct. 31, 1903) shows what an elaborate and savory meal can be gotten up from breadstuffs, fruits and vegetables while, on the other hand, a more simple and easily obtained meal could hardly be desired. There is no doubt but what a large number of the chronic ailments which we are called upon to relieve are due to overeating, especially when a proteid diet is freely indulged in. The chief advantage of bread and fruit diet is seen in the collemic and high blood-pressure group of uric acid food poisonings. Such used to be called diseases and were reckoned under the names of headache, epilepsy, neuralgia, asthma, Bright's disease, dropsy and obesity. The great point in the relief of these troubles is the lowering of the blood pressure. By cutting down the fluids as much as possible and feeding on breadstuffs and fruit, a blood pressure of 150 to 160 mm. of mercury can be reduced in a week or two to 120 mm. of mercury with a correspondingly large improvement in all the forms of food poisoning. The washing-out plan of treatment by giving large quantities of water to drink usually fails, for it does not increase the elimination of uric acid and furthermore maintains the high blood pressure which is an important causative factor in the conditions. In many of these high blood pressure troubles much good may also be done by temporary but complete abstention from both food and fluid, as this will produce in twelve to twenty-four hours, a fall of from 20 to 40 mm. of mercury in the blood pressure.

Alimentary Glycosuria in Children of Diabetic Persons.—Heredity undoubtedly is an important factor in the causation of diabetes which seldom develops suddenly or rapidly in a perfectly healthy individual. Since its symptoms do not usually appear until the disease has advanced to some degree, it is only by some chance such as an insurance examination that the cases are discovered in their early stages. A. LORAND (Practitioner, Oct., 1903) has carefully examined ten

cases of children or young adults, one of whose parents, at least, has a well-developed diabetes mellitus. It was found that although several of them showed no traces of sugar in the urine on a restricted diet they all showed distinct glycosuria when given a test meal containing from 250 to 300 grams of carbohydrates. Care was taken to eliminate the possibility of this glycosuria being due to the ingestion of any drugs. He believes that the majority of children of diabetic parents have inherited a certain defective power of dealing with sugar in their economy, and if this fact was known early in life their lives might be greatly prolonged by a careful regulation of their diet. He has also noticed in such persons the presence of acne vulgaris not only in the years of puberty, but also in full grown-up adults. Obesity was also frequent among them and according to v. Noorden this is a symptom of diabetic predisposition. This does not mean that all people showing these predisposing signs will have true diabetes, but if addicted for a long time to an irrational nourishment (containing an abundance of meat and sweet, amylaceous food), or if subjected to great psychical emotions they are much more liable than the ordinary individual to develop diabetes and the younger they are when this appears the more serious will be the prognosis.

SURGERY.

Some Peculiarities of Temperature in Appendicitis.—Several authors pointed out some time ago the great divergence of temperature in appendicitis between that taken per rectum and the axilla, the difference ranging between 1° to 2.9°, while in severe cases an increased frequency of the pulse was observed with a fall in the temperature. M. I. Rostovtzeff (Roussky Vrach, Oct. 4, 1903) noted a maximum rise of temperature in light cases (namely, those that recovered without surgical interference), between four and six o'clock in the evening, while in a smaller number of these cases the maximum rise occurred at 9 to 10 P.M. On the other hand, in the more severe, operative cases, the highest rise in the temperature was noted at between nine and ten o'clock in the evening; the same rise was observed in the very severe, fatal cases. The author desires the above data to be considered as important, in conjunction with other symptoms, in the diagnosis as well as the prognosis of the case. He advises frequent temperature taking particularly toward evening, and in case of a rise between nine and ten o'clock in the evening our watchfulness should be redoubled.

Malignant Diseases of the Larynx.—Abernethy said: "Every operation which mutilates is a black spot on surgery." Thermistokles Glück (Med. Jour., Oct. 31, 1903), said that in operating upon the larynx, our first object must be to save life, our next to leave the patient in such a physical condition that the life thus saved was worth living. For some of the cases of syphilis and circumscribed cancer of the cords, the steps recommended are as follows: (1) A low tracheotomy is done; (2) a median incision is made through the skin and fascia, the sternal muscles are retracted and the larynx is exposed; (3) the thyroid cartilage and cricothyroid membranes are divided in the middle line and the two halves retracted with hooks; (4) a solution of cocaine and antipyrene five per cent. and carbolic one per cent. in water is applied to the anterior of the larynx and the growth is removed with scissors, knife or thermocautery, and plugs of iodoform gauze are placed in the larynx and fixed with a few points of sutures through the cartilage. (5) Between the fourth and sixth days the plugs are removed under anesthesia. In three weeks healing is completed and the patient is allowed to speak. The operator has patients who were operated upon fourteen years ago who are still able to lecture regularly.

Appendicular Toxic Nephritis.—This condition, although too little known, expresses itself by one constant sign—albuminuria. Prof. Dieulafoy (Med. Press, Nov. 4, 1903) regards this lesion as one of extreme importance. The nephritis often escapes observation owing to the absence of obvious symptoms, more particularly in the event of the albumin being present in but moderate excess and where that most graphic symptom, the swelling in the region of the eyes is absent. In these cases the urine should be watched very carefully for granular casts, and if they are discovered, the prognosis is rendered much more grave. Albuminuria in itself does not always justify us in giving an unfavorable prognosis, but it is nevertheless one of the signs of impending toxemia and should be regarded as an important danger signal. This is not due to the nephritis alone, which in some cases may lead to anuria and to general intoxication of the organism. It is interesting to note the possibility that the nephritis due to appendicular toxins may be a factor in the etiology of chronic nephritis, or, indeed, spreading further, it may in cases of chronic appendicitis be a prominent factor in the etiology of general cirrhosis.

Treatment of Fractured Mandible.—So many methods have been devised in the interest of this frequent fracture as to show that the ideal has not yet been reached. Stewart L. McCurdy (Ann. of Surgery, Nov., 1903) drills from the external surface into the sublingual cavity. The drill holes should be made between the apices of the second and third teeth in the line of fracture if possible, so as to guarantee firm anchorage. On being made they are threaded with a notched drill and the wire passed through from without into the mouth on one side. The free ends are twisted on the outer surface of the bone so as to bring the margins in perfect apposition. Iron wire is always used, being tougher, less irritating and in every way superior to silver wire. These patients soon learn to hold their teeth together, and the wire, without any other dressing, is left in for about six weeks. The question of feeding this class of patients is one of some concern. Where no teeth are absent, it has been customary to pass a glass tube back of the last teeth. If the curve is sufficiently marked, nutrition can be more readily maintained by the increased ability of the patient to close the lips and suck up fluids.

Prostatic Hypertrophy.—The rôle played by the enlarged prostate from its earliest symptoms until death closes the scene is purely mechanical. George W. Hawley (Ann. of Surg., Nov., 1903) concludes from the analysis of the problem of prostatic hypertrophy (1) that it is not the prostate, but the adjacent urinary tract which demands treatment; (2) that the direct cause of the interference with the urinary evacuation is the displacement of the outlet of the bladder resulting from enlargement of the retrourethral portion of the prostate; (3) that until the precise cause of prostatic overgrowth is known and successful preventive measures employed, one can only hope to relieve this condition by correcting the displacement; (4) that until an effectual method is devised, which is sufficiently safe and simple for application, before infection and disorganism of the urethral tract has resulted, surgery cannot bring any great relief; (5) that the logical mode of correcting vesico-urethral displacement by reduction is evinced by the fact that operative methods improve urinary evacuation by virtue of their power to reduce this displacement; (6) that while some of the methods partially, sometimes completely, accomplish reduction with comparative safety, and others entirely reduce it, but at con-

siderable risk, none does so with both safety and success; (7) that since the reduction of the vesico-urethral elevation is essentially a mechanical problem, reduction based on anatomical and mechanical processes should prove the simplest and safest. No method can be successful which does not permit of complete reduction for all degrees of elevation. The operations of Dr. E. W. Andrews and H. Delageniere are based upon correct principles, but do not go far enough. The author describes in detail a more complete technic for the downward reduction without injury to the bladder and urethra.

Renal Calculus Simulating Sciatica.—It is important that every person who is a chronic sufferer of malaria and who gives a history of having had it for a number of years, particularly if the patient be young, should be examined for possible renal calculus. H. E. BRUCE PORTER (Lancet, Oct. 17, 1903) records an interesting case in which a prominent practitioner had been misled into believing the case one of idiopathic sciatica, and had subjected the patient to the annoyance and futility of a three years' stay at Carlsbad. This patient became pregnant at the age of thirty-one years and during the whole period suffered intensely from a pain in the right side. The hands swelled so much that she could not wear her rings. She was given to understand that this was due to her pregnancy, and her urine was not examined. At the time of examination, four years after the birth of the child, the urine was loaded with pus, about three drams in twenty-four hours. It was free from tubercle. Sir Frederick Treves operated on the patient, and upon the removal of the kidney it was found to be nothing more than a mere shell containing at least 15 ounces of pus.

Upward Dislocation of the Foot.—The literature of this subject is extremely sparse. The salient features of the condition are that the astragalus, retaining its normal relations with the foot, is driven upward between the tibia and fibula without fracture of either bone. PERCY W. G. SARGENT (Lancet, Oct. 17, 1903) cites a case from St. Thomas' Hospital. Reduction was accomplished under an anesthetic by simple traction on the foot. This dislocation is one of the most remarkable, because of the enormous strength of the ligaments uniting the parts. On the cadaver the dislocation could not be imitated until not only the interosseous, but the internal and external ligaments of the ankle had been divided. This seems to show that this accident had taken place in the case cited, although the recovery was complete. The more important clinical notes on this case are (1) the increase of the intermalleolar measurement; (2) the prominence of the heel; (3) the approximation of the maleoli to the plane of the sole; (4) the absence of fracture; (5) that the injury was not compound; (6) the extreme ease with which reduction was effected.

Splenectomy for Banti's Disease.—Osler describes this symptom complex as "a chronic affection, probably an intoxication of unknown origin, characterized by a progressive enlargement of the spleen, which cannot be correlated with any known cause, a marked tendency to hemorrhage, particularly from the stomach, and in many cases a terminal stage of cirrhosis of the liver, jaundice and ascites." C. H. LEVISON (Ann. of Surg., Nov., 1903) relates the interesting history of a case occurring in a young man upon whom he had previously operated for appendicitis and whom, after the development of the characteristic symptoms of Banti's disease, he was able to follow technically for eight months. The blood findings characteristic of Banti's disease are (1) oligocythemia, the average number of red cells being 3,500,000; (2) oligochromia, the low percentage of hemoglobin is fairly constant and is marked by a low color index. In pernicious anemia the contrary obtains. (3) leucopenia. This is quite constant. The leucocyte count is usually much under 5,000. The red cells in the differential count are of no value. Levison's summary of his case is as follows: First, that the disease was preceded by an infectious appendicitis. Second, that there were intervals of perfect health interrupted by profuse bleedings. Third, the exacerbations of temperature of the leucocytosis both indicative of some form of infection. Fourth, slate colored stools and diarrhea, evidences of a digestive disturbance. Fifth, severe pains between the shoulder blades, enormous quantities of morphine necessary for its relief. Sixth, the spontaneous disappearance of the ascites after a single paracentesis. Seventh, the splenectomy followed by the rapid increase in percentage of hemoglobin. Eighth, the appearance of normoblasts and megaloblasts in the blood subsequent to the splenectomy. Ninth, the rapid regeneration of a very abnormal blood. Tenth, the disappearance of the melanoderma. Eleventh, thrombosis of the veins of the neck. The author concludes that Banti's disease offers a favorable prognosis if operated upon early, death resulting if it be allowed to pass unoperated.

Hallux Valgus.—Tight-fitting or narrow-toed shoes are probably only a small factor in the causation of this condition. It seems to occur in people whose feet are of one type: Arch of the foot well formed, the extensor tendons of the great toes prominent at the metatarsophalangeal joints, the first phalanx of the toes extended and the distal phalanx flexed. J. G. SHELDON (Med. Rec., Oct. 24, 1903) believes that the tendon of the extensor proprius hallucis muscle by its insertion tends to abduct the big toe, and that as soon as the abduction begins this muscle acts with greater force. This muscle is always strong and is found tense in cases of hallux valgus. The operation which is recommended for this condition is the modified Dawbarn operation. The joint is exposed by making a flap, the convexity being upward and outward. Instead of resecting the whole head of the metatarsal bone, the inner one-half or two-thirds of the head is removed by bone forceps, the outer part of the head being undisturbed. The extensor tendons of the big toe are then split and divided so as to allow a lengthening of from an inch to an inch and a half. The advantages of the operation are that a movable joint is obtained without shortening of the toe, while lengthening of the tendons prevents recurrence of the deformity.

Modified Operation for Inguinal Hernia.—In doing a radical operation for hernia it is almost universally admitted that the separation of the hernial sac is the most difficult part of the operation, and the trauma which is often caused may result in unpleasant consequences. S. PETRULIS (Archiv f. klin. Chirurg., Vol. 71, No. 4) advocates the method first proposed by Kasumowsky in which the sac is left in place. The operation was done in twenty-one cases without recurrences, and consists in the main of a resection of the hernial sac at its neck, after the latter has been sufficiently separated from the cord, and a closure of the opening in the usual manner. In two cases there was a subsequent accumulation of fluid in the sac after the eleventh day, but this disappeared in about two weeks without any complications.

Effect of the X-rays on Epithelial Tissues.—An investigation relating to the penetrating power and the effect on normal tissues of the Roentgen rays has lately been made by G. PERTHES (Archiv f. klin. Chir., Vol. 71, No. 4). Among other things he was able to show by microscopical examination that the action of the X-rays was much more intense on the epithelial cells

than on the adjoining connective tissue. It must be assumed, however, that the carcinoma cells are altered to a greater extent than those of the normal epidermis, for in this way alone can the rapid proliferation of normal epithelium be explained which covers over the small defects resulting from the disintegration of carcinomatous nodules. The author also claims that the rays possess greater penetrating properties than have hitherto been attributed to them. In two cases of inoperable mammary cancer, degenerative changes could be detected in the deeper layers of the growth after exposure to the rays. In a number of other instances warts were covered with skin from corpses and exposed, with the result that in every case the wart disappeared. Another series of experiments was concerned with the effect of the rays on active growth. It was found that when newly hatched chicks were exposed to the rays, their growth was markedly inhibited. On the side exposed the development of the feathers and the growth of the long wing bones was appreciably inhibited when compared with the other side. It seems that the rays in this case are not intense enough to kill the cells, but merely inhibit growth. Whether this is due to direct action on the cells or is produced by the intermedium of chemical products, still remains an unsolved problem.

Question of Early Operation in Appendicitis.—An interesting contribution to this widely discussed subject is made by Prof. E. Payr (Archiv f. klin. Chir., Vol. 71, No. 4), in which he gives due credit to American efforts in this particular branch of surgery. From a careful study of the subject, and the result of his own experience, he finds that the statistics of the so-called early operation for appendicitis are based on widely varying collections of material, and cannot, therefore, furnish conclusions which are applicable in all cases. An increasing number of surgeons acknowledge the necessity of early operation in that class of cases where the appendix is directed in a medial direction from the cecum, and thus affords a readier means for the spread of an inflammatory process. The author believes that it is important to develop this point in topographical diagnosis, and to bring into proper relation the clinical picture with the pathological changes. He concludes that if the appendix has been removed before perforation or abscess formation has taken place, the operation cannot be designated as an "early" one, but should be considered as having been undertaken in the nick of time. If the operation is done after perforation occurs, the chances of recovery may be compared to those in perforating gastric ulcer or a ruptured gall-bladder.

Case of Duodenojejunal Hernia.—A very novel pathological condition, which has hitherto been apparently unnoticed in the literature, is described by A. Narath (Archiv f. klin. Chirurg., Vol. 71, No. 4). A laparotomy was undertaken in a young woman in whom the clinical diagnosis of tumor of the pyloris or gall-bladder had been made. Exploration showed the presence of an old ulcer of the stomach followed by pyloric stenosis, hour-glass contraction of the stomach, and also a very peculiar displacement of the entire small intestine. The latter did not occupy its usual position below the transverse colon, but ascended upward back of the stomach, perforated the lesser omentum and then descended in front of the stomach, the transverse colon and the greater omentum down to the lower part of the abdominal cavity and the pelvis. The colon was normally placed and fixed, and only the cecum was displaced toward the center and upward. When the small intestine was reflected upward, the lower section of the ileum could be detected coming through an opening in the median line at the root of the transverse mesocolon. The entire small gut could be readily pulled through this opening and replaced in its normal position. The author explains this extraordinary condition by assuming that originally there was present a retroperitoneal hernia, the sac of which ruptured upward and back of the stomach, forming a true left-sided hernia of Treitz. The hour-glass contraction of the stomach may be explained by the action of the loops of gut which surrounded the organ in a circular manner and the author also calls attention to this condition as an etiological factor in the production of hour-glass contraction. Operation in the case in question consisted in replacing the abnormally situated gut and sewing up the opening through which the gut had found its way. The pyloric stenosis was treated by doing the usual form of pyloroplasty and the patient made a good recovery.

Foreign Bodies in the Male Bladder.—As is well known, no pathognomonic symptoms exist whereby to determine the existence of this condition. Exact diagnosis is possible only by objective methods. Occasionally the diagnosis is easy—when, for example, the physician has had the misfortune to break off an instrument in the bladder during manipulations, but as a rule, conditions render a diagnosis on subjective data very questionable. Maximilian Hirsch (Deut. Zeitsch. f. Chir., Sept. 1903) outlines the following directions for examination: (1) Palpation, under anesthesia bimanual through rectum. Perfected by v. Volkmann, but useless if the prostate be enlarged; (2) sounding has a wider field. By this method much can be learned, not alone as to the existence of a foreign body in the bladder, but yields information as to the number, size, shape, consistence, position and motility; the presence or absence of incrustation or pocketing; (3) lithotrite, an excellent idea of the consistency of the foreign body may be had from the use of this instrument and very often particles come away attached to the blades. (4) cystoscope. This instrument enables position, orientation and identification of the body, as well as the condition of the bladder wall, as to inflammation, bands, etc. (5) X-rays. These are particularly useful in cases, particularly of extreme stricture of the urethra. Unfortunately this method is useful in those cases only where the foreign body is of such a nature as to cast a shadow. The therapy of this emergency depends entirely on full diagnosis of existing conditions. There are two methods of choice: The wet and the dry. The history of these for the past fifty years is interesting. After the introduction of the lithotrite the percentage of removals via the urethra rose from 27 per cent. to 82 per cent. With the advent of aseptic technic it has returned to 27 per cent. The choice of the dry methods is determined (1) by the relation of the sizes of the body and the urethral orifice to each other; (2) the body must be freely movable; (3) it must be free from sharp sides or points; (4) it must not be too brittle; (5) the urethra must be free from extensive stricture; (6) extensive cystitis contra-indicates; (7) if iron, a magnet may be used. The wet method, either by the supra- or infrapubic route is indicated (1) when the dry fails (2) in all other conditions, except those cited above. It should be remembered that the infrapubic route does not open the bladder proper, being virtually an external urethrotomy. Hence the suprapubic path is usually preferred.

Treatment of Traumatic Hemorrhage of the Spleen.—The difficulties attending the treatment of this condition are commented on by N. Senn (Jour. Am. Med. Ass'n., Nov. 21, 1903), who proposes a method which he has successfully experimented with in dogs. In a number of these animals clean-cut, incised wounds

of the spleen were made, calculated to give rise to a maximum amount of hemorrhage. The edges of the wound were then seized with broad forci-pressure forceps, which were very slowly closed. This action displaced the splenic pulp from the loose net work of connective tissue, which, in turn, is condensed into a broad, firm band in which the larger blood-vessels become entangled. The forceps may be left in place for several minutes and then the crushed margins of the wound are sutured together with catgut. In all cases (7) subsequent autopsies showed that the wounds had healed with good results, and that very few adhesions were present. Based on the results of these animal experiments he regards this as the most favorable procedure yet devised.

Resection of the Intestine.—A series of nine cases is reported by G. T. Vaughan (Am. Med., Nov. 21, 1903) with five recoveries and four deaths. Five were done for strangulated hernia with three recoveries and two deaths, and four for tumor of the colon, with two recoveries and two deaths. The methods were by the Murphy button, five with three deaths; and suture three, all recoveries. In one case the ends of the intestine were left ununited. The button was used in the worst cases, while the suture was used only in the most favorable cases. The high mortality (44 per cent.) is accounted for by the severity of the cases operated upon.

Thrombosis of the Femoral Veins and Laparotomy.—The majority of the writers on this subject consider that infection is the most probable cause, says E. R. Secord (Am. Gyn., Oct., 1903), though, as Willy Meyer puts it, the infection need not start from the operation field, but may originate elsewhere especially in the intestinal tract. In a large percentage of the cases, however, neither wound infection nor inflammatory disturbance in other parts of the body can enter into the discussion, since nearly all the wounds followed a typically aseptic course, and in many at least there was no evidence that there were infective lesions elsewhere. The elevated temperature is not in itself an evidence of an infective origin (Meyer). All writers on this complication have emphasized its late occurrence. Nothing new can be offered regarding the treatment of this state when it arises. Elevation of the limb and moist heat to favor the formation of the necessary collateral circulation seems best to meet the indications. Lennander's suggestions as to prophylaxis by elevation of the foot of the bed would seem difficult to carry out. Moreover, it would surely make 999 patients uncomfortable in order that one might have the chance of escaping this complication. Again, Van Buren Knott reports 326 cases of laparotomy treated postoperatively by elevation of the head of the bed (Fowler's position), without any increased tendency to phlebitis. It would seem advisable to support the abdomen more securely, especially after removal of large tumors, than is now the general practice. After hernia operations it would appear best to exercise a certain degree of direct pressure over the wound area, probably best carried out by a well-applied spica of crinoline. No single etiological factor is alone responsible for the occurrence of this complication. The rôle of infection in otherwise non-infected cases does not seem to be an important one. Conditions of sudden decrease of pressure independent of the operation probably exert a causative influence. Treatment should be prophylactic by avoiding all unnecessary traumatism, hemorrhage or a sudden decrease of tension, by having the wound area well supported by firmly applied bandages. So far as the author is aware, there has been no mortality in the reported cases, but the occurrence of pulmonary embolism in a certain proportion of cases warns us that this termination is not an impossible one.

Intussusception in Children.—Much has been said regarding the difficulties of diagnosing this condition, and it is altogether likely that, in some cases, especially in the enteric variety, this is true. But in three cases reported by R. E. Skeel (Am. Gyn., Oct., 1903) the diagnosis was at all times easy to make, was entirely typical; there were paroxysmal, colicky pains of great severity, prostration, vomiting, tenesmus, and bloody stools in all. In addition, the abdomen was soft and could be palpated with ease, so long as the child did not cry. A tumor could be found in the same locality in each of them, but was frequently elusive in that it could be distinctly made out and the next moment would escape entirely from the grasp, only to be found again after a somewhat prolonged search. An extremely severe attack of colitis was the only other condition that could be confounded with it, but the soft, flat abdomen would have been sufficient to have at once put one on his guard. The positive evidence afforded by the presence of a sausage-shaped tumor was, of course, of great value in arriving at a diagnosis, but it was merely confirmatory. It is an open question whether cases reduced by mechanical measures would not have reduced themselves, but these methods are of value in classifying cases at the earliest possible moment, and indicating the necessity for surgical intervention in those which fail to yield to such measures. All arrangements should be made and consent gained before the operation, and a fair trial of air or water should be given. If they fail to cause complete disappearance of the tumor, no time should be lost, for the earlier the operation the more effectual will be its results. Repeated attempts at mechanical reduction are not only useless, but dangerous, and give more time for swelling an edema of the intussusception and for adhesions to occur, and perforation and peritonitis to take place, and this loss of time might convert a simple into prolonged and complicated operation, ending in death.

Surgery of the Ileocecal Valve.—The fact is well established that the pyloric and rectal valves are liable to inflammatory disease, with consequent hypertrophy and contraction of the tissues and attendant partial obstruction of the tract. N. Stone Scott (Am. Jour. of Obstet., Nov., 1903) thinks that it would be most natural to suspect the other one of the three, the ileocecal valve of similar tendencies. Again the pyloric end of the stomach is rich with glandular structures, and it is in this part of the stomach that we find gastric ulcers with the resulting cicatricial contractions and stenoses. So of all parts of the intestine there are more glands at the ileocecal valve. Both in typhoid and tuberculosis there are to be found more ulcerations than elsewhere. The medical history of the subject is remarkable for its silence. Legg reports but six cases of non-malignant stenosis of this portion of the intestinal tract. Schröder showed two cases at autopsy and Sayo reports but two others. The symptoms and signs of a contracted ileocecal valve are quite obscure, there being no pathognomonic symptoms, but merely a combination of those noted for appendicitis and obstruction of the intestine proper. A chronic ileocecal obstruction will more likely be mistaken for a chronic appendicitis than for chronic obstruction. The following are a few of the more important signs and symptoms: Periodical pains at McBurney's point, with thickening of the tissues, sometimes to such an extent as to form a good-sized tumor. Tenderness of the same point sometimes accompanied with rigidity of the abdominal muscles. Pain in the stomach, acid or gaseous eructions, and other dyspeptic symptoms. Disturbances of the bowels,

usually constipation, or diarrhea, followed by constipation. Evidences of distention of the lower end of the ileum, the presence of which is best evidenced by the hard tumor in the iliac fossa, which comes and goes, usually accompanied by colic-like pains, sometimes disappearing with gurgling sounds. Not all these symptoms are present in every case; in fact, the larger majority of them may be absent, thus leading to greater obscurity. The etiology of the cases is usually either hyperplastic valvitis or ulceration, the result of typhoid or other disease. Since the ileocecal contraction sometimes appears coincident with the more common chronic appendicitis, and especially as many of the symptoms are identical, it is right that the surgeon should examine the valve while operating for appendicitis. Non-malignant obstruction of the ileocecal valve, though not more prevalent than heretofore, will be far more frequently recognized, and therefore rectified, in the future than in the past.

Intra-abdominal Rupture of the Urinary Bladder.—In concluding his very elaborate article on this subject J. B. Zeldovich (Roussky Vrach, Oct. 18, 1903) reports the case of a woman who was kicked in the abdomen and suffered at once from severe pain, incessant vomiting and retention of urine. The condition of the patient when conveyed to the hospital was that of a severe shock, with a subnormal temperature, rapid, small pulse, dry tongue, inflated and painful abdomen. As the urine drawn by the catheter did not contain any blood a diagnosis of a traumatic peritonitis was made, but which abdominal organ was injured could not be definitely settled before the operation. Laparotomy decided the diagnosis; the injured organ was the ruptured urinary bladder. This was sewed up, and a comparatively uneventful recovery followed. The author embraced the opportunity of giving a very interesting historical review of the subject, which will undoubtedly be very instructive to the specialist, but which does not admit of abstraction.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Inflammatory Foci in Bone.—By injecting the vascular system of the various bones with a mass made up of mercury triturated with oil of turpentine, E. Lexer (Archiv f. Chir., Vol. 70, No. 1) was able to secure Roentgen-ray pictures which clearly showed the course of the vessels and also the presence of the site of different infectious emboli. It was found that tuberculous foci in most cases are the result of infectious emboli or small masses of bacteria. Their favorite site is in the epiphysis or metaphysis of the long bones, although foci in the diaphysis may also arise from emboli which find their way through the nutrient artery. The connection between a trauma and a tubercular focus may be explained by a scattering of an old bone focus, although there is a possibility that a tubercular embolus or mass of bacilli may be accidently deposited at the site of the injury to the bone. Pyogenic foci are likewise of embolic origin, at least in part. The prevalence of staphylococci as causes of a purulent osteomyelitis may be explained by their tendency to be propagated in small masses. In this way a true bacterial embolus may be formed at the point where a single coccus is deposited, especially in the minute capillaries in the region of the zone of growth in the long bones. In both cases the greater vascularity of the bones of young persons plays an important role in determining the presence of inflammatory lesions.

Mortality Due to Congenital Malformations.—An attempt at an analysis by modern statistical methods, of certain biological aspects of the death-rate in man due to congenital malformations, has been made by R. Pearl (Medicine, Nov., 1903). He bases his studies on the mortality returns in the last United States census, and the specific problem investigated may be stated in the form of a question as follows: Is there any evidence that, with respect to all abnormalities sufficiently great to cause the death of the individual possessing them, one sex is more variable than the other? An analysis of these figures shows that the mean age of death from fatal congenital malformations of the sorts included in the census returns, is essentially the same in man and woman. Hence it may be safely concluded that the mean intensity or degree of the malformations is not essentially greater in one sex than in the other. The variation in the age at death from such malformations, as measured by the standard deviation and the coefficient of variation, is significantly greater in women than in men, and hence we may conclude that in intensity or degree of the malformations woman is more variable than man. These figures apply, of course, only to the United States returns, and may not hold among other peoples, and it would, therefore, be impossible to formulate any general rule, and it is necessary to study each particular species living in a certain environment. The author also calls attention to the fact that the mortality from congenital malformations discussed in this paper forms an excellent example of the action on the human race at the present time of natural selection "by the elimination of unfavorable variations."

Amitotic Cell Division.—Formally it was believed that amitotic cell division was restricted to the lower animals, but recently numerous observations have been recorded where direct cell division was found in both normal and pathological conditions in the higher vertebrates and man. R. Caminiti (Virchow's Archiv, Vol. 174, No. 1) found almost all the cells in a rare solitary adenoma of the liver multiplying by the direct process. The cells resulting from amitosis are probably equally as resistant as those generated by karyokinetic division, and it is wrong to suppose that they are only found in degenerative processes. The factors which determine the kind of division are yet unknown. Instances of karokinesis in the avertebrates, where amitosis is the rule, are also common.

Amyloid Tumors.—The first instance of amyloid tumor of the lung is reported by G. Herxheimer (Virchow's Archiv, Vol. 174, No. 1). The patient was an old man who had long suffered from hoarseness, and rather suddenly developed an empyema of obscure etiology. At autopsy one lung was studded with numerous small foci of greenish-yellow, hyaline appearance. The empyema probably resulted from suppuration of one of these tumors. The larynx was so altered by a similar pathological tissue that the true and false vocal cords were entirely destroyed. Microscopic examination revealed an alveolar connective tissue in the meshes of which a structureless tissue was imbedded, which gave a distinct amyloid reaction. Amyloid degeneration always begins in the media of the arteries; in many cachectic conditions it occurs as a general lesion, but local tumors are exceedingly rare. Sometimes part or the entire organ is involved, or syphilitic scars, malignant tumors and abscesses show amyloid foci, but real tumors have only been described in the bladder, conjunctiva and upper respiratory passages. They are always covered by normal mucous membrane, and at the periphery the lumen, adventitia and intima of the vessels are often apparent. The pathogenesis of these tumors is still unsettled; some look upon them as a result of a syphilitic inflammation, while others believe there is first a connective tissue new growth, which secondarily undergoes amyloid degeneration. In the author's case syphilis was de-

nied. The amyloid substance probably results from an exudation into the interstices of the connective tissue; it consists chiefly of proteid matter and chondroitin sulphuric acid, so that it may possibly be derived from the elastic fibers of the organs. The author found these fibers well preserved, but pushed apart in the peripheral parts, but in the older portion they gradually disappeared. In conclusion a new selective stain is described. The sections are placed into a concentrated solution of ponceau in alcohol, sodium hydrate and water for half to several hours, then washed in 70-per-cent. alcohol and stained with hematoxylin. The amyloid will appear pale or dark red, the nuclei blue and fat more yellowish-red.

Thyroid Gland in Smallpox.—The lesions of the thyroid gland in smallpox do not differ from those found in other acute infectious diseases, according to H. ROGER and M. GARNIER (Virchow's Archiv, Vol. 174, No. 1). They are characterized by an increase in colloid secretion so that the vesicular arrangement is absent, and the proliferating cells are placed closely together without order. Hemorrhages within the parenchyma are not infrequent. With exception of the latter the changes are purely functional and it is a peculiarity of the thyroid gland that functional disturbance gives rise to altered histological appearance. In severe cases the hypersecretion may be followed by an exhaustion of the gland, so that little colloid is present. When the patients survive the acute infectious disease, this exhaustion may explain subsequent thyroid disease as yet of doubtful origin.

New Method of Preserving Specimens.—By placing anatomical specimens into a supersaturated solution of ammonium sulphate and then passing illuminating gas through the fluid, M. CLAUDIUS (Virchow's Archiv, Vol. 174, No. 1) could preserve the natural colors more perfectly than with other methods. The gas converts the hemoglobin into the carbon monoxide compound and the salt preserves this and fixes the specimen by coagulating the albumin. It is necessary to preserve the organs in an airtight jar since the air will again break up the compound and give rise to a more brownish discoloration. All shades between red and brown can be obtained by regulating the amount of air. Bile pigment is also preserved and the normal consistence is retained. If animal specimens are to be preserved, it is simply necessary to kill the animal with illuminating gas and then place the organs into the salt solution.

Heat and Local Irritants.—In attempting to account for the beneficial action of both these agents, a series of practical experiments have been made by K. WESSELY (Archiv f. klin. Med., Vol. 71, No. 2). His point of view is based on the assumption that the antibodies in the blood serum have an important action in the beneficial effects produced by an hyperemia. This required an answer to the question as to whether the antibodies of the blood serum entered the tissues from the vessels in greater quantities during the production of a hyperemia. His experiments were conducted on the eyes of rabbits. After carefully shaving the eyelids, applications of hot water were made, the temperature of which was gradually increased from 50° to 60° C. It was found that the albumin content of the aqueous humor was increased from about $^1/_{10}$ per cent. in the normal condition, to $^3/_{10}$ and even $^1/_2$ per cent. As the hyperemia of the vessels in the ciliary bodies resulted in this increased transudation of serum albumin, it is natural to suppose that the total quantity of antibodies was also increased. This was also experimentally proved—a rabbit was treated with subcutaneous injections of dog's blood. The humor from a normal eye had no effect whatever in dissolving the corpuscles from a dog's blood, but that taken from an eye which had been subjected to warm applications for half an hour, readily dissolved them. The same effects were also observed in experiments made on the conjunctiva. The conclusion drawn from these experiments is that the therapeutic effects of an hyperemia are due at least in great part to the increased collection of antibodies in the affected tissues or organs.

NEUROLOGY AND PSYCHIATRY.

Extensive Brain Loss Without Impairment of Intellectual Faculties.—The famous crowbar case has always been cited as evidence that there may be severe injury to the frontal lobes without much disturbance in brain activity. Confirmation of this belief is found in a case reported by W. KEATE (Med. Rec., Oct. 17, 1903). A miner was struck by a premature explosion while standing bent over the hole. Both eyes were blown out, the bones of the roofs of the orbits were driven into the brain, and the skin and muscles from the forehead were torn off. There was a hole in the frontal bone about the size of a ten-cent piece. The brains were exuding from these openings. The openings were smoothened and enlarged and twenty small stones and several pieces of bone were removed from the anterior portion of the brain. At least an ounce of cerebral matter came away. The patient has never for one moment been unconscious. He answers all questions intelligently and accurately describes the details of the accident. He has never complained of pain, and says that his head feels paralyzed.

General Paralysis of the Insane.—Some extremely interesting data on paralytic dementia are communicated by B. S. GREIDENBERG (Russ. med. Rundschau, No. 14, 1903) covering a period of observation extending over ten years of very active asylum practice. He has some years ago pointed out that paralytic dementia is on the increase, and especially so among women, the proportion being 10 to 5, and never less than 10 to 4. Attention was also drawn to the fact that the disease is no longer a city disease, for it is gradually invading even villages and small towns. In the city the affection grows what he calls more and more "democratic," attacking the lowest strata of society, again largely women. As the chief causative factors of general paralysis the author considers syphilis, alcohol and heredity; although syphilis is found in a preponderating proportion of cases, it nevertheless cannot be considered as the only etiological factor of the disease. The present article embraces the results of investigations covering a period of twelve years, during which time the author had under treatment the enormous number of 7,090 insane patients, among whom 800 were general paralytics, forming 11.28 per cent. of the entire number. It is interesting to note that among the low classes of society the women form a majority of patients attacked with general paralysis, while higher up the number of men is twice that of women. As regards occupation the common unskilled laborer heads the list, followed by the peasant, merchant and official, professional, skilled laborer, and so on down the list. Sixty per cent. of the entire number were made up of married people, while unmarried formed but 15 per cent. Etiologically syphilis was found in over 50 per cent. of the cases, alcoholism in 38 per cent., the rest was heredity, psychical emotions and traumatic influences.

Manhattan Dermatological Society.—The following officers were elected for 1904: I. P. Oberndorfer, M.D., President; E. L. Cocks, M.D., Vice-President; A. Bleiman, M.D., Secretary and treasurer.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, DECEMBER 19, 1903.

HERBERT SPENCER.

IN common with all scientific men the members of the medical profession have good cause to mourn the passing of Herbert Spencer. Although he was not a contributor to medical science in any but the most general way, he was the great exponent of the philosophy of all science—the one man who has done the most to dignify the claim of science to be the final arbiter and adjuster of the thoughts of men. In the death of Mr. Spencer the world loses the last of that great group of scientific leaders of whom, with Darwin and Huxley, he may be said to have formed a great triumvirate in the English-speaking world.

The great merit of Herbert Spencer, if we do not misapprehend him, was not so much in the specific results of his labors as in his method. All his conclusions will not go unchallenged, but in the vast survey which he took of the domain of human knowledge he supplied a scientific organon which will survive so long as men remain true to the teachings of inductive science. Spencer was an evolutionist before Darwin, and in the principle of evolution he found a method which is not confined to mere biology, but which is fruitful in results in psychology, sociology and ethics. The whole panorama of human thoughts and human interests passed in review before that master mind, and were subjected to an analysis which points to the final attainment by mankind of a satisfactory scheme of the knowable. Beyond that impassable bourn Spencer never attempted to penetrate. He was satisfied with the universe as it lay before him. His merit consists preeminently in the fact that he taught men the limits of rational science.

That there will be a reaction from Spencer is inevitable, and the signs of it were visible for some years before his death. The metaphysical and theological mind will not rest content with the knowable. It must seek to penetrate the veil—which possibly only hangs in front of a blank wall. The fate of science, and with it possibly the fate of modern civilization, may depend more than we perceive on the courage with which scientific men adhere to the principles of Spencer. That the battle is not yet won must be apparent to the student of the tendencies of the times. There are reactionary forces at work always and their activity makes all the more deplorable the loss of this luminous and gigantic mind.

Already it is pointed out with a kind of gleefulness that Spencer's work was not without flaws. His psychology and his sociology do not always stand the test of criticism and increased knowledge. We are told that he was not an original investigator—that he was a bookman, a schoolman, who merely took what others gave him. Such criticism merely skims over the surface of his work. Beneath all lies the substructure of pure thought, and over all lies the illumination of a great beacon light of scientific method. The details can be altered or shifted as the progress of science may require, but the system will remain a true reflex of human knowledge.

In his personality Herbert Spencer was the type of the modern philosopher. As was said of Marcus Aurelius, he lived without delusions. In his death the world suffers an irreparable loss, but his bequest to mankind is an example of high living and accurate thinking, which the world will ignore at its peril. For the medical profession he was an example and an inspiration, and it owes him the tribute due to a great scientist.

UNCHARITABLENESS OF THE CHARITY ORGANIZATION SOCIETY.

THE Charity Organization Society has done much to assist the medical profession of this city in its efforts to restore to health those sufferers

from disease who are unable to pay for necessary care and treatment. The scope of the work of this organization is very broad, and the assistance it furnishes to those in ill health is but one of its aims. Yet the doctors connected with our dispensaries and charitable institutions are fully alive to the great need of more help in caring for the sick-poor, and welcome and encourage any and all who offer their time, or money, or influence. Perfect harmony should certainly exist between the doctor, who has since the time of the father of medicine, been the friend of the unfortunate, and those who would be philanthropic and charitable.

It is, therefore, with deep regret that we notice a most uncharitable utterance in "Short Stories," a little book published by the Charity Organization Society and sent out with their recent appeal. The sixth story is headed, "The Story of How We are Disappointing Doctors." It is a tale of kind treatment and appropriate medical care given by a nurse, with happy results, to a sufferer from consumption. We do not find in the story itself any character such as a "disappointed doctor," and the inference would be that the writer thinks doctors are disappointed by having cures take place.

Charities, the weekly publication of this organization, will doubtless try to make amends editorially for this uncharitableness toward a profession which is nothing if not charitable. It is not that medical men care for their own feelings —they are too broad-minded for that—but such a heading is repulsive to all who have felt the sympathy and kindness of a physician—and who has not?—and the appeal is likely to bear little fruit.

We do not believe Mr. de Forest, Mr. Morgan, Mr. Bannard or Mr. Devine would have permitted this error had they seen the proof sheets.

THE NEW ANTITUBERCULOUS SERUM.

Notwithstanding the almost total failure of Marmorek's antistreptococcus serum to accomplish the remedial effects originally claimed for it, the announcement that the young Austrian bacteriologist who, for nearly ten years, until quite recently, has been connected with the Pasteur Institute in Paris, had discovered a new serum for tuberculosis, attracted world-wide attention in medical circles. On November 17 last, at the meeting of the Academy of Medicine in Paris, Marmorek made a definite announcement of the details of the method by which his new serum is prepared and the line of thought that has led him up to its discovery. We have had an opportunity to see an early copy of his original paper, and while we fear that his first announcement of results is, as is usually the case with remedies for tuberculosis, overenthusiastic, we feel that our reader's interest in the subject and certain suggestive details of the biology of the tubercle bacilli and its toxin justify our giving the new remedy and theory some attention.

Many of those who were present at the International Medical Congress at Paris in 1900 will recall the fact that Marmorek presented a paper to that body in which he described the various types of tubercle bacilli which he had classified in his laboratory at the Pasteur Institute. He dwelt particularly on the cultural characteristics of the microorganisms and demonstrated that tubercle bacilli retained their primitive characteristics only for a short time after being transferred to an artificial medium. It is in the tubercle bacilli grown in artificial media that the toxin called tuberculin, originally discovered by Koch, is formed. There are many reasons for doubting that this is the real toxin produced by the tubercle bacillus when it grows in animal tissues. Small amounts of tuberculin produce no reaction in healthy human beings. They produce, however, a very serious reaction in those suffering from even minimal lesions of tuberculosis. Finally, small injections of tuberculin produce very little effect on animals or human beings suffering from very severe forms of tuberculosis. Marmorek considered that this series of contradictions quite justified him in rejecting the notion that tuberculin was the true toxin of tuberculosis.

His effort was to secure the growth on artificial media of tubercle bacilli that would retain their primitive characteristics. In human beings and in animals the tubercle bacillus normally has its habitat either in leucocytes or in giant cells. Marmorek accordingly tried to grow the tubercle bacilli in the presence of leucocytes freshly obtained from animal tissues of living animals. He failed, however, to secure the persistence of the primitive characteristics of the tubercle bacilli by this method, as it is very difficult to secure growths of the bacilli. His next step was to prepare a leucotoxic serum. This was secured by injecting the white cells of small animals into the calf and afterward withdrawing its blood serum. On this he was able to secure a rather

abundant growth of tubercle bacilli. He had noted, however, that in laboratory animals, as also in human beings, in cases of generalized tuberculosis, the liver is usually the last organ attacked and is often found free from the disease. There seems to be some special resistive quality in its substance then. He argued that this quality could be used to increase the vitality of tubercle bacilli.

Accordingly, to his leucotoxic serum he added bouillon made from liver substance to which a slight amount of glycerin was added. Grown on this glycerinated leucotoxic liver bouillon the tubercle bacilli did not thrive well except by careful selection of what seemed to be hardy colonies. Bacilli that did grow, however, retained their primitive characteristics much longer than on any other artificial medium and failed entirely during their growth to produce any tuberculin, though they did produce another characteristic toxin. By the use of graduated doses of this toxin, Marmorek was able to obtain some immunity to tuberculosis in the lower animals, so that after a time the leucocytes were not only englobed, but digested tubercle bacilli were injected into the animal and so kept it immune from the effects of the microorganism.

By graduated doses of this product the blood serum of the animal acquired antitoxic qualities and this could be used for the protection of other animals and for hastening the cure of tuberculous lesions, especially in rabbits, which are not so sensitive to tuberculosis as guinea-pigs. Very large doses of the serum have to be employed for this purpose, but these animals present little resistive vitality to the disease, and in the larger animals and man it was hoped that their natural resistive powers would so aid the action of the serum as to require smaller doses. In nearly two thousand cases now the serum has been used on human beings in the hospitals of Paris and in various parts of France. Necessarily, at first only hopeless cases could be secured for purposes of observation. Even with regard to these cases the results were so satisfactory as to tempt physicians to further experiments.

Many of the symptoms even of tuberculous meningitis are relieved by the injections of the serum. The paralysis lessens, the coma disappears, the fever is less marked and the vasomotor symptoms are diminished. So far, however, no case of meningitis has been cured. In severe cases of pulmonary tuberculosis with cavities and abundant expectoration, with many bacilli, the beneficial effect is noted very soon after the injections have begun. The expectoration lessens in amount, the number of bacilli decrease and the patient's general condition improves. Some of the apparently hopeless cases are practically cured, though sufficient time has not elapsed to absolutely announce a cure. In milder cases of pulmonary tuberculosis, the effect is immediate and striking. Hectic fever disappears rapidly under the treatment and night-sweats and the loss of appetite consequent upon the fever disappear with it. Hectic fever, far from being the contraindication to the use of the serum, constitutes a very favorable condition for the demonstration of its efficacy and these cases have been particularly sought out by Marmorek and his assistants in order to make the value of the serum clear.

It is in cases of surgical tuberculosis, however, that the serum is claimed to give the best results. In complicated Pott's disease, with abscesses and fistulæ, rapid improvement is noted shortly after the injections are begun. Hip-joint disease is as favorably affected as is Pott's disease, and abscesses are absorbed without delay and any unfavorable sequelæ under the influence of the antituberculous serum. Marmorek considers most of the cases of idiopathic pleurisy as of tuberculous origin. In this he is justified by many bacteriological tests of the injection of apparently the simple serous transudate of pleurisy into animals with the consequent development of tuberculosis. Pleurisy is rapidly benefited by the serum in Marmorek's hands. The exudate is rapidly absorbed, the pain and discomfort, and especially the dyspnea, are diminished and the patient's general health, if at all run down, improves under the serum injections.

Unfortunately, in the hands of observers outside of France the new serum has not proved so beneficial as in its inventor's. Some German investigators have even reported harmful results from its use. Marmorek's resignation from the Pasteur Institute is said to have been due to a disagreement with his colleagues over the preparation of the serum for commercial purposes, its exploitation in the press, and some doubts as to the results obtained with it. Generally, in Paris medical circles there is an air of incredulity with regard to it. While the subject is of interest it is doubtful if any great hopes should be raised because of it. Some of the work done may be as valuable as it is interesting and suggestive. As Marmorek himself says, at the conclusion of his article, many more observa-

tions under varying circumstances will have to be made before its true place in medicine can be appreciated. Though life is almost as short as in Hippocrates' time, art is quite as long, and we must be patient.

THE PROTOZOON OF SCARLET FEVER.

Before the Boston Society of Medical Sciences, on Tuesday evening, Dr. Frank B. Mallory described, with the aid of microphotographic lantern-slides a protozoon which he supposes is the infective cause of scarlet fever. The supposed animal was found in the skin of four cases of this dire disease, sometimes in the lymph spaces, but most abundantly in the epithelial cells of the corium close to the epidermis.

In many essential respects the organism is somewhat like that now known to be the occasion of malaria. It appears in two forms, one a radiated rosette and the other a granular form with a knotted reticulum not unlike that of the nuclei of certain animal cells. The rosettes are apparently at first about two micromillimeters in diameter, circular in appearance or often elliptical. On the center of each is a small rounded mass which stains opaque with methylene blue. Radiating from this central mass are from ten to eighteen segmented spindles each with an enlargement at its peripheral end. In what appear to be later stages of development of this object the rosette has enlarged somewhat and the segments separated from each other, while in still later stages some of the now strongly club-shaped segments have become loosened from the central mass and appear as independent dots of deeply stained tissue. Later on these seem to have developed granulations, and arranged themselves often in clumps of four. There are evidences in the appearance of these segments that when fixed in the Zenker's fluid they were in ameboid movement. The later stages of the rosettes and clumps often have a diameter of ten or twelve micromillimeters.

Dr. Mallory found it difficult, in many cases of the disease, to find these bodies, the skin area being so large. No desquamative stage showed any, and they could not be found in any of the liquid discharges of the patients. The protozoa seem especially abundant in the papillæ of the skin, and in the superficial lymphatic vessels. For this new parasite their discoverer suggests the name *Cyclastis scarletinalis,* as fairly descriptive of their form. That these objects are not artefacts appears from the circumstance that of three bits of skin from one case, all stained in the same vessel at the same time, one specimen had many of the rosettes, one few, and one none, while in the very numerous preparations of skin similarly made in the study of the germ of smallpox nothing of this nature whatever could be discerned. Dr. Mallory closed this, his preliminary report, by saying that while he personally believed this to be the infectious agent of scarlet fever it had not as yet been actually proven. To his large audience and numerous observers of his photographic preparations made from cases, the impression was strong that the occasion of this now most feared of children's infectious fevers has indeed at last been detected, and that, almost in the act. If so, another of the bêtes noires of parents is probably started on the road to vanquishment by the skill and energy of modern medicine, although until some medium on which a pure culture of protozoa may be raised is discovered, the production of a certain antitoxin for scarlet fever, as for smallpox, may be delayed.

ECHOES AND NEWS.

NEW YORK.

Gift for Public Charities.—A merchant of Maiden Lane who recently aided in the conviction of a thieving public stores employe received from the Government a check for $500. This he has divided into parcels of $100 each and given to the following charities: The Police Pension Fund, the Montefiore Home, the Presbyterian Hospital, the United Charities, and the Educational Alliance. A very neat tribute to a very worthy cause.

Lectures on Alcohol and Opium Inebriety.—Dr. T. D. Crothers, of Hartford, Conn., Professor of Mental and Nervous Diseases at the New York School of Clinical Medicine will deliver a course of four lectures on "Inebriety from Alcohol, Opium and other Narcotics," January 5 and 6, 1904, at 4 P.M. and 8 P.M. in the hall of this school, 328 West Forty-second Street, between Eighth and Ninth avenues, New York City. The medical public are cordially invited to attend.

To Vaccinate New York.—The Board of Health in this city is taking vigorous steps to prevent an outbreak of smallpox in New York, and to that end has appointed 64 new inspectors, who will co-operate with the large force of regular inspectors in searching for persons who have not been vaccinated. Many cases of smallpox have been reported lately in Philadelphia, Pittsburg, Allegheny, and other cities in Pennsylvania, and the New York City health authorities are determined that a similar outbreak shall not be felt here. Dr. Lederle said last Monday that the additional corps of 64 inspectors had been engaged purely as a matter of precaution. "There is not," he said, "any reason to believe that this city will be visited by an epidemic of smallpox. Our purpose is to nip the disease in the bud, and the new members of our corps will assist the other inspectors in visiting all of the schools, tenement houses, department stores, and other places where people are congre-

gated and are, therefore, liable to exposure. Of course, a case of smallpox is apt to crop out now and then, but there is no reason whatever why the disease should spread, if proper measures are taken at the outset."

Insanity in Colorado.—Colorado is facing the situation of insufficient provision for its insane. The Pueblo asylum is overcrowded, and the Denver County Hospital is caring for 119 such patients, in a building designed for about half that number.

The Associated Alumni of the Mount Sinai Hospital.—The following resolutions were adopted by this body: Our honored president and companion, Dr. Edward Fridenberg, has passed from among us in the fulness of life and activity. We recall with pride the fame he had achieved in the practice of his profession, and the esteem in which he was held by his patients. We recall his unusual kindness, his generous courtesy, his sweet companionship, his broad fairmindedness, his remarkable breadth of character, his great love of humanity and above all, his great love for children. His culture and his love of the beautiful dominated his life and thought, his qualities made his life an example which we shall always cherish. A copy of this shall be sent to the family and to each of the New York City medical papers. For the Association: Samuel M. Brickner, M.D.; Edwin Sternberger, M.D.; William H. Luckett, M.D.

Manhattan Dermatological Society.—Regular monthly meeting held on Friday evening, Dec. 4, 1903, at the residence of Dr. J. Sobel, Dr. L. Weiss, presiding.

Dr. W. S. Gottheil presented a case of seborrheic eczema (shown at November meeting) involving hairy parts of the face, chin, upper and lower lips, eyebrows and eyelids. Marked improvement, following the use of sulphur and resorcin ointment, is seen; the eczematous condition is very much paler, the pus follicles diminished and the scaly element reduced.

Dr. C. W. Allen was of the opinion that many of these cases begin as a primary lesion in the nose. He saw just such a condition following chronic rhinitis and ozena; the irritating nasal secretions setting up a dermatitis of the upper lip and from here infection spreads to the hair follicles and also spreads to distant parts of the face, being conveyed by means of the patient's fingers or handkerchief. The involvement of the follicles was secondary and often severe enough to resemble sycosis. In the treatment he advocated swabbing of the nasal cavities with 25 to 50 per cent. aq. sol. ichthyol. For the dermatitis the X-ray. Dr. Crary agreed with Dr. Gottheil in calling it seborrheic eczema with secondary folliculitis. Dr. Abrahams took some exception to Dr. Allen's remarks, inasmuch that the majority of patients with chronic rhinitis never show involvement of adjacent or contiguous skin structures. He looks for another cause in such cases; probably the bacillus of pseudo-erysipelas; this site being a favorite seat for such infection. Although willing to admit some cases might come under Dr. Allen's statement, this case is probably of different origin.

Dr. Weiss suggested epilation of the vestibulæ nasi and application of 2- to 5-per-cent. nitr. silver solution, for the nasal complication; sulphur and resorcin ointment for the eczematous condition. He also spoke favorably of the X-ray.

Dr. B. F. Ochs presented a case for diagnosis. A male of thirty years with a chronic affection of the nails of 8½ years' duration. About nine years ago patient had an eruption on inner aspect of thighs, scrotum and buttocks. Dr. Ochs inclines to the belief that this eruption was an eczema marginatum, and from this patient subsequently infected his nails. All the finger-nails were involved and some of the toe-nails. The nails were cracked, brittle, scooped out (spoon-shaped) and ridged.

Dr. Gottheil considered three conditions: favus—this, he thought, could be excluded; in favus he expected to see greater undermining of the matrix with consequent pressure atrophy and more deformity of the nails. Psoriasis, as an isolated lesion was extremely rare; nevertheless it should be thought of. Ringworm—this he thought most probable to be the case in this patient. The microscope might decide the question, although admitting that microscopical examination of the nails was very unsatisfactory.

Dr. Weiss said the condition was undoubtedly parasitic; the diagnosis of nail affections was a difficult chapter, as no positive information could be deducted from microscopical findings. In making a diagnosis he would be guided in a great measure at least by clinical signs and the history.

Dr. Allen would call to his aid the microscope. Although he suspects this case to be one of tricophytosis, one should not lose sight of the possibility of its being favus; the latter is a much more common nail affection than we suppose. He saw favus of the nails, when no other lesion was present anywhere on the body. The source of infection and mode of contamination in such cases was as obscure as it was interesting. In favus cases he usually finds a small, yellowish spot somewhere beneath the middle of the nail, which microscopically shows almost a pure culture of spores. Drs. Cocks and Crary believe the condition to be parasitic. Dr. Oberndorfer called it tricophytosis; most probable. He expected to see greater scaling and more pronounced lesions if it were psoriasis, chronic eczema might be considered, but the absence of eczematous lesions elsewhere rather excluded such a diagnosis. It was undoubtedly parasitic. Dr. Bleiman stated that the microscopic picture would probably be different when scrapings or nail sections from the fingers and toes were compared, owing to the different existing conditions. The fingers being exposed, cool and dry, while the toe-nails are confined and subject to heat and moisture. The differential diagnosis between favus and tricophytosis, even with the aid of the microscope, was no easy task. Dr. Allen said he recognized the favus spore by its larger size and more oval shape. Dr. Abrahams remarked that he saw a condition which resembled present case in a housewife, whose hands were exposed to water and soda. The condition being one of traumatic chronic eczema due to excessive moisture, constant irritation and maceration.

In the patient exhibited no such etiological factor existed, and hence he looks for a parasitic origin.

Dr. Crary showed a photograph of an infant ten days old with favus lesions on scalp and elbow, contracted from its mother, whose lesion was on the scalp.

PHILADELPHIA.

Phipps Institute Lecture.—The third lecture in the series under the auspices of the Phipps Institute will be given December 29 in Witherspoon Hall by Dr. G. Sims Woodhead, of England, Professor of Pathology in Cambridge University and a member of the Royal Commission on Tuberculosis. The subject of the lecture is to be "Paths of Infection in Tuberculosis."

Compulsory Vaccination at University.—The Provost of the University of Pennsylvania has officially written to the dean of each department making

compulsory the vaccination of every member of the teaching body, every member of the student body and every employe who has not been successfully vaccinated within the last five years.

The Statue of "The Medicine Man."—The statue of "The Medicine Man" was during the past week formally presented by the Fairmount Park Art Association to the city of Philadelphia. The statue, which represents a young Indian, equipped in proper insignia, mounted upon a saddleless horse, has been placed at the head of Strawberry Hill, in East Park.

Plans for Medical Inspectors Partly Approved.—Upon the recommendation of Finance Committee, which reversed its first action, Common Council has approved an appropriation of $60,000 to the Bureau of Health to carry out, partially at least, the plans of Director Martin for reorganizing the system of medical inspection. It is believed that Select Council will concur. The request for 25 nurses was not allowed.

Intussusception During Typhoid Fever.—An interesting case of this lesion was reported at the meeting of the Philadelphia Academy of Surgery December 7 by Dr. G. G. Ross. The patient was a boy who, about the twenty-fifth day of an attack of typhoid fever and after having several hemorrhages, developed symptoms of perforation. He was operated upon a few hours after the onset of symptoms but on opening the abdomen no evidence of peritonitis was visible. Examination of the lower portion of the ileum revealed no perforation. Further search resulted in the discovery of an intussusception three inches in length at a point three feet below the junction of the duodenum and jejunum. The invaginated gut was easily reduced. The patient is now well on the road to recovery, although he had several hemorrhages after the operation.

Pancreatic Calculus.—Dr. G. P. Müller reported this case at the Pathological Society December 10. The lesion was found post mortem in a man of sixty years, who was admitted to the German Hospital while critically ill and died three days later. No history of his past or present illness could be obtained. The cause of death was apparently pulmonary tuberculosis. All the biliary ducts were found to be patulous, but the duct of Wirsung was occluded by a large number of closely packed calculi, some of which were nearly a centimeter in length. They gave the reaction of calcium carbonate. The parenchyma of the pancreas was almost entirely replaced by fat, the islands of Langerhans being uninvolved.

Trypanosoma Lewisi—Drs. W. M. L. Coplin and A. G. Ellis exhibited specimens, in stained preparations and in fresh blood, of *Trypanosoma Lewisi*. The parasites were at first secured through the kindness of Dr. Novy, of Ann Arbor, but later specimens for inoculating purposes have been secured from wild gray rats caught within the enclosure of the Philadelphia Hospital. Of 23 specimens from that institution 10 contained the parasites in large numbers. Broadly speaking, the young rats were found to be infected and the old ones uninfected. Rats from other sections of the city have not been examined. Of 16 wild rats from Asheville, N. C., five were found to contain the parasites. Studies are being made of the tissues of infected rats with as yet no positive results, except in one instance, which may be of considerable significance. In the lung of an infected rat which had died was found quite large areas of distended vessels and hemorrhage which practically amounted to infarction. This fact is of interest in connection with the recently reported case of atypical pneumonia in a person who was suffering from trypanosomic infection. Although the parasites could not be demonstrated in the vessels, the occurrence of these hemorrhagic areas suggests the possibility of pulmonary infarction in cases of infection by the parasite.

Hydrophobia Still Unknown to the Coroner.—At the recent meeting of the Philadelphia County Medical Society, Dr. G. M. Illman reported a case of hydrophobia with autopsy. Dr. Illman deplored the fact that the disease has no official recognition in the city and is not even generally recognized by the medical profession. When he returned the case in question, the coroner's office refused to accept his certificate of death from hydrophobia and insisted on classifying it as due to extreme hysterical convulsions following the bite of a dog. The patient had refused to undergo the Pasteur treatment until the symptoms of the disease had made their appearance. Dr. Illman argued in favor of muzzling dogs and also of quarantining them at all seasons of the year when they show signs of illness. In the discussion Dr. M. P. Ravenel said that in addition to his experience with human beings he had demonstrated beyond a doubt in more than 150 animals that hydrophobia is a distinct disease.

American Roentgen Ray Society.—The fourth annual meeting of this Society was held in Houston Hall, University of Pennsylvania, on December 9 and 10. A very instructive exhibit of apparatus was made and papers were read by many of the best known X-ray workers of the country. Variable results were reported, some having met with disappointment in the therapeutic effect of the agent in question, others reporting very satisfactory series of cases. Among the Philadelphians who read papers were Drs. W. M. Sweet, C. L. Leonard, G. E. Pfahler, W. H. Newcomet, M. K. Kassabian, and H. K. Pancoast. The address of President Goodspeed was upon "The Trend of Modern Thought Upon the Subatomic Structure of Matter." The meeting of 1904 will be held in St. Louis. The officers elected were: President, Dr. James B. Bullitt, of Louisville; secretary, Rr. Russell H. Boggs, of Pittsburg; treasurer, Dr. Weston A. Price, Cleveland; first vice-president, Dr. John B. Murphy, Chicago; second vice-president, Dr. Charles L. Leonard, Philadelphia; third vice-president, Dr. Edwin E. King, Toronto; executive committee, Dr. Preston M. Hickey, Detroit; Dr. Kennon Dunham, Cincinnati.

CHICAGO.

Suicide Increase is Great.—An alarming increase in the number of cases of homicide during the last year is shown in the annual report of Coroner Trager. More than 50 per cent. of the fatalities the Coroner charges to the practice of carrying concealed weapons. Interesting data concerning the gloomy work of the office is also shown by the report. During the year 459 suicides were reported and investigated. Of these, 239 were of married people, from which the Coroner argues that more unhappy persons are to be found in the dual state than in single life. Of 225 suicides who died by poison, 169 ended their lives by taking carbolic acid. The Coroner's office investigated 6,053 cases during the year, arranging for 3,194 inquests. Next to self-destruction, railroad accidents claimed the greatest number of victims—350—nearly half of these being slain at crossings. While more cases were investigated during July than any other month, the greatest number of suicides occurred during September, reaching as high as 46. March is also a bad month for suicides, having a record of 44. The

greatest number of deaths reported to the Coroner occurred between the ages of 30 and 40.

Health Matters.—Although the November (1903) mortality was below the average of the previous ten years, 13.71 and 13.80 per one thousand respectively, the month has not fulfilled the hope that it would continue the decreased rate of the previous five months, and so offset the high rate of the earlier months of the year. The probabilities now are that the total deaths for the year will be in the neighborhood of 28,400 and that the death-rate, computed on the Chicago Health Department's conservative estimate of 1,885,000 population, will be about 15 in the thousand. This will be higher than that of any year since 1899, when the rate was 15.56 per thousand. The week's mortality was unusually low for the season of the year; compared with that of a year ago it shows a 12.5 per cent. decrease in proportion to the population. The causes of death showing the most marked decrease are Bright's disease, consumption, pneumonia, scarlet fever, and typhoid fever. The acute infectious diseases all show a reduction in the number of deaths and in the number of cases reported.

Sympathetic Ophthalmia.—Dr. Oscar Dodd reported this case at a recent meeting of the Chicago Medical Society. He emphasized the necessity of care in watching any case of injury that sympathetic inflammation may not develop, and the danger of passing over any trouble in the other eye, however slight, as being a simple matter. He laid stress particularly on the hopelessness of treatment in these cases, as no severe case had ever been cured.

Pregnancy Following an Operation in which the Right Ovary was Removed, Left Ovary Resected, and the Round Ligaments Shortened Intra-abdominally.—Dr. Anna M. Braunwarth read a paper on this subject before the Chicago Medical Society, Dec. 9. The points of interest in this case may be summarized as follows: A case of cystic degeneration of the ovary, and retroversion of the uterus, one ovary having been removed and the other resected, and the round ligaments shortened intra-abdominally. Within four months after her recovery from the operation, the woman became pregnant and was delivered of a full term child, with normal labor. The vomiting of pregnancy ceased as soon as the pessary was removed. During her puerperium the temperature rose to 104° F., due to retained secretions in the uterine cavity, and subsided after curetting. The shortening of the round ligaments intra-abdominally intertered in no way with carrying the child to term, or with delivery. The case teaches that resection of ovaries is not opposed to pregnancy; that cystic degeneration does not necessarily prevent normal ovulation and conception, and that a pessary retained as a uterine support may prove to be an irritant, which will cause severe vomiting in pregnancy.

Permeability of Rubber Drainage Tubing to X-ray.—Dr. Joseph F. Smith read a paper on this subject before the Chicago Medical Society. The following investigation was carried out at the suggestion of the late Professor Christian Fenger, and is based upon a case which occurred in his service at the Presbyterian Hospital in the latter part of the year 1900. Miss C., aged twenty-nine years, was admitted to the hospital suffering from an extensive tuberculous abscess in the region of the right iliac synchondrosis, which had previously been opened and drained without improvement. The patient was anesthetized and through an extensive incision part of the right ilium was resected, and an extensive tuberculous abscess found in the right iliac fossa. From the abscess two sinuses were discovered, one leading upward along the psoas muscle toward the upper lumbar vertebræ and the other leading downward into the cavity of the pelvis. These sinuses were isolated and explored as far as possible, and drained by means of No. 8 Nelaton catheters, one being placed in the upper sinus to a depth of eight or ten inches, and the other to an equal depth in the lower sinus. Both were brought out through the external incision at the same point, and secured by fastening with safety pins, and a large absorbent and protective dressing applied. A few days later, when dressing the patient, it was discovered that one of the catheter drains had disappeared from the wound, the other being still in place. Careful search failed to reveal the presence of the drain in the dressings, and the special nurse in charge of the patient, upon being carefully questioned, declared positively that the tube had not fallen out during any of the dressings. The conclusion that the tube must have slipped into the wound and been lost in the abdominal cavity or in the cavity of the pelvis seemed most probable. After going over the facts carefully, Professor Fenger decided to reopen the wound and make careful search for the missing drain, and accordingly ordered the patient prepared for operation. On the day set for the operation it was decided to take an X-ray picture through the region in which the rubber drain had been placed, to see if any shadow of the missing tubing could be obtained; although at that time it was not thought probable the rubber tubing would cast a shadow of sufficient density to enable it to be seen through the thickness of the body. However, a skiagraph was taken and contrary to expectations a very distinct and definite shadow of the upper tube was obtained. Since the drains were both exactly the same size and kind of material, both being No. 8 Nelaton catheters, it seemed a certainty that the second tube should also show if still present within the body. Skiagraphs were made of the entire abdomen, from the pelvis to the diaphragm, but no shadow of the second drainage tube was obtained. It was decided, therefore, that the tube must have slipped out and been lost in the dressings, notwithstanding the positive assertion of those in charge of the dressing of the patient to the contrary. The exploratory operation to search for the missing tube was abandoned, and the patient went on to an uneventful recovery. The fact that the tube used for drainage in this particular instance produced such a distinct shadow with the X-ray made it desirable to ascertain whether or not all of the kinds of rubber drainage tubing in common use produced shadows that enabled them to be distinguished through a considerable thickness of tissue, and if not all, what particular kind of drainage tubing produced the most distinct shadow. For this purpose samples of pure gum, plain white, corrugated white, and maroon tubing of the same size and thickness were obtained. These with a No. 12 Nelaton catheter were arranged side by side upon a cardboard, and a skiagraph taken through the thigh of a boy eight years of age. In the skiagraph the red catheter rubber gives a very dense shadow; the plain white, corrugated white tubing, cast a distinct shadow, the maroon a somewhat less distinct shadow, while the pure gum tubing produces scarcely any shadow at all. Since various metallic compounds enter into the composition of rubber tubing, it becomes a matter of interest to compare equally thick layers of metallic compounds and their solutions. For this purpose paper boxes having a depth of one centimeter were dipped in melted paraffin to render

them impermeable to solutions, and filled with finely pulverized salts of various metals, and also ½ gram molecule solutions of the same salts. These salts and solutions, prepared by Professor Walter S. Haines and Dr. Frick, were arranged in order upon a plate and exposed to the X-ray. The negative shows that different metallic salts differ widely in their permeability to the X-ray, and that this same difference extends also to their equivalent solutions. It appears also that the permeability depends upon the nature of the positive radical and varies inversely as the atomic weight of the metal forming the positive radical. This matter, however, requires further investigation with a large number of salts and careful tabulation of results before perfectly definite statements can be made. Although some work has been done along this line by Trowbridge and others, further investigation is necessary to clear up the matter definitely. A comparison of the densities of the shadows cast by the salts and solutions shown in the skiagraph explains the variation in density of the various kinds of rubber drainage tubing. The bright red catheter and stomach tubing contained vermilion (mercuric sulphide), HgS, and it will be seen from the skiagraph that the compounds of mercury cast very dense shadows. The maroon tubing contains vermilion (HgS), or sulphide of antimony (Sb_2S_3), generally the latter. The white tubing contains salts of lead or zinc, chiefly lead oxide (litharge, PbO), and these metals cause the tubing to cast quite distinct shadows, though not so heavy as the maroon and red tubing. The pure gum containing no metallic compounds, or only traces of them, cast a very faint shadow when shown through any considerable thickness of tissue. The practical conclusion to be drawn from the facts above stated pertains to surgical work chiefly. In the drainage of cavities or long sinuses, there will be a distinct advantage in the use of rubber drainage tubing that produces a distinct shadow with the X-ray, especially in cases where there is any danger of the drain slipping into and being lost in the cavity or sinuses. For diagnostic purposes also there is a certain practical bearing, because red rubber catheters, stomach tubes, etc., passed into passages of the body, as the esophagus, for example, show in the skiagraph the extent to which the passage is patulous.

GENERAL.

Dr. Finsen is Ill.—A report from Copenhagen, Denmark, dated Dec. 11, states that Dr. Finsen of that city, to whom the Nobel Medical Prize was awarded by the Norwegian Parliament on Dec. 10, is dangerously ill.

Yellow Fever in State of Mexico.—The Texas Health Department is advised that no new cases of yellow fever have appeared at Monterey, Tampico, and other places in Northern Mexico for several days. The Texas quarantine against those places will be raised in a few more days. Dr. Eduardo Liceaga, President of the Superior Board of Health of Mexico, has requested the Mexican Congress to make an appropriation of $100,000 to be used in combating yellow fever on the Gulf coast of Mexico next season. Dr. Carillo, Vice-President of the Board of Health of Monterey, announces that there were about 10,000 cases of yellow fever in that city during the recent epidemic, and that there were 580 deaths from the disease.

The Nobel Prizes.—Although the award of the five Nobel prizes for 1903 does not conform closely to the forecast cabled to this country in October its propriety will be quickly perceived by those best qualified to have an opinion in the matter. More than one perplexing situation has been met with striking sagacity, justice and good taste. Without question the most important work done in physics in the last few years has been in the study of radiation. Two years ago Roentgen received the Nobel prize for his investigations in that field, and last year Lorentz and Zeeman, two Dutchmen, divided the honor. The judges who made the choice this time naturally thought of M. and Mme. Curie. They were aware, too, that in all probability neither polonium nor radium would have been discovered so soon but for Becquerel's observations of the strange properties of uranium eight or nine years ago. Not only is radium obtained from the same ore, pitchblende, but the first characteristic of it which attracted attention was its ability to emit an invisible radiance like that of uranium and the vacuum tube. It was, therefore, decided to put Becquerel on a par with his compatriots. On previous occasions a prize has been divided between two persons, and now three share one. While the pecuniary effect of that arrangement is not so satisfactory as it might be, the honor is the chief desideratum, and that is in no way diminished by division. It is noteworthy, too, that, though Becquerel and the Curies are chemists, their recent researches are looked upon primarily as contributions to physics. Arrhenius, the Swede, who wins the prize in chemistry this year, has well earned it. His text-book in electrochemistry is not only one of the most recent but also one of the most authoritative works on that subject. Moreover, he is the author of the theory of ions, which has been advanced to explain the dissociation of substances by electricity. This was first propounded in 1888, but was so revolutionary in its suggestions that time was needed for its full acceptance. Even yet it does not command unanimous support. Still, in formulating the doctrine, Arrhenius is believed to have rendered valuable service to chemistry. Finsen, of Copenhagen, has been so favorably known through his experiments in healing with electric light that it was generally expected a year ago that he would be honored as he is now. No one needs to be told who Björnsen is, or why he receives the literary prize. The public will certainly approve that award, and many people will feel peculiar joy on discovering that he has not been compelled to share it with Ibsen, as at one time seemed possible. Finally, there will be no doubt about the fitness of according to Mr. Cremer, for thirty years the secretary of the International Arbitration League, the prize for devotion to the cause of universal peace. One of the most interesting phases of the distributions which have been made by Nobel's trustees during the last three years is the nationality of the recipients. Owing to the division of several prizes, nineteen persons in all have been recognized. It will be noticed that the Scandinavian race, of which Nobel himself was a representative, was ignored until this year, and now Sweden, Norway and Denmark are simultaneously complimented. Certainly, there is no chance here for an imputation of partiality. Four Germans, five Frenchmen, three Dutchmen and two Englishmen—Mr. Cremer is the second—are included in the list. The latter is completed by the addition of one Russian and a single Switzer. As yet America and Italy remain unrecognized, but their turn may come next year.—N. Y. *Tribune.*

The Journal of Comparative Neurology and Psychology.—The *Journal of Comparative Neurology*, as originally announced, was open to contributions in the fields of comparative neurology, physiology and psychology. The founder, feeling that the time was ripe for a more thorough correlation of the facts in these different fields, planned to devote the journal as much to the functional as to the structural study of the

nervous system. During the thirteen years of the existence of the *Journal of Comparative Neurology*, the functional side of neurological work, although not wholly neglected, has received far less attention than was originally contemplated, chiefly on account of the continued ill-health of the editor-in-chief, who had intended to devote himself primarily to comparative psychology. Now, however, the editors announce an enlargement of the editorial staff which will insure a more satisfactory representation of the functional as well as the structural aspects of neurology. The journal will hereafter be known as the *Journal of Comparative Neurology and Psychology*. The organization of the editorial staff remains in general as before save that Dr. Robert M. Yerkes of the Department of Psychology, Harvard University, will be the responsible editor for the department of Animal Behavior. He will be supported on the editorial board by representative students of Comparative Psychology and other departments will be strengthened by the addition of collaborators. The attention of psychologists, physiologists and medical practitioners is called to the fact that this is the only journal in any language especially devoted to this large and important field of research. It is aimed to make the journal indispensable to all who are interested in the structure and functions of the nervous system from whatever point of view. They will find much of value in the materials published, for in addition to the recognized fact that the human nervous system can be best understood structurally by a study of its phylogeny, it is now clear that an understanding of the reactions of lower organisms and especially of the evolution of action, is necessary for an appreciation of the functional significance of the human nervous system. For morphologists the journal will continue to be, as in the past, the *vade mecum* in its department. Hereafter the journal will appear bi-monthly, and each annual volume will contain about five hundred pages. The first number of the new volume is to be ready in February. Every effort will be made to secure as prompt publication of acceptable contributions as is consistent with the high standard of scientific and mechanical excellence which has been maintained. Contributions will be accepted in English, German, French or Italian. The subscription price will be $4.00, strictly net (foreign subscriptions $4.30, 18s., M.18, 22fr., L.22). All present subscribers to the *Journal of Comparative Neurology* will receive the volume for 1904 at $3.50. Complete sets of back numbers may still be had at the original price of $3.50 per volume. Numbers are sold separately at prices varying with the contents.

Obituary.—Dr. Elisha Hall Bridges, a prominent physician and medical expert, is dead at Ogdensburg of acute Bright's disease. For years he had been head of the Medical Association in that city. He was sixty-two years old, and is survived by his wife, a daughter, and a son, Attorney Henry W. Bridges, of New York.

Dr. Cornelius N. O'Leary, of 560 West One Hundred and Thirty-third Street, who was killed by a motor train at New Utrecht Avenue and Fifty-seventh Street, Brooklyn, on Saturday night, was buried from his late residence on Tuesday last. Dr. O'Leary was born in Ireland sixty-four years ago, and came to this country with his father when a boy. After graduating from the College of Montreal, he attended the University of the City of New York, and graduated from the Medical Department in 1862. Upon the death of his father in 1864 he succeeded him as professor of philosophy and classics at Manhattan College, which chair his father had occupied since the organization of the college. In 1870 he was connected with the Board of Health in the capacity of inspector, and resigned that position to become a Commissioner of Pharmacy in 1871. He wrote for various periodicals, evolution being one of his favorite subjects. He was a great admirer of Herbert Spencer, and one of his articles, entitled "Evolution in the Light of Recent Research" is well-known in scientific literature.

SOCIETY PROCEEDINGS.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held October 14, 1903.

The President, William H. Park, M.D., in the Chair.

Pathological Anatomy of the Shiga Bacillus in Infections of the Intestines in Infants.—Dr. John Howland presented a paper on this subject. The organism found in all the cases examined was the type known as the acid-producing or Flexner-Manila organism; that is, it fermented glucose and saccharose, but not lactose, and split mannite with acid formation. It produced an early acidity in milk with a subsequent alkalinity, and agglutinated with the "Harris" serum in high dilutions. Thirty-two cases were examined. From a study of these cases it seemed that they could be grouped with considerable accuracy according to the histological findings. Group A, comprising five cases, represented the severe infections where the pathological changes were of a pseudomembranous type. The membrane may be of irregular distribution or very extensive, involving both the colon and the ileum. The pseudomembrane was composed chiefly of necrotic tissue, desquamated cells and countless bacteria. Fibrin was present in very small amounts or not at all. There was a necrosis of the mucosa and it was this necrosis which chiefly gave the appearance of a false membrane; but in all these cases the necrosis did not extend beyond this coat. In the necrotic tissue and at its border there were hemorrhages, and thromboses, and it was divided from the healthy tissue by a zone of small cell infiltration, containing both mono- and polynuclear cells. The submucosa in four of the severe cases was much swollen and infiltrated. The cellular infiltration was composed of cells resembling Unna's plasma cells and was most marked about the blood vessels. The muscular coat showed only a slight mononuclear cell infiltration. The peritoneal coat was normal. Group B included four cases in which the mucous membrane in both the small and large intestines were in a good state of preservation. The changes occurred chiefly in the lymphoid follicles. The submucosa was normal as were the muscular and peritoneal coats. Group C includes those cases characterized by superficial necrosis and ulceration in the mucous membrane not limited to the follicles as in Group B, and not accompanied by the formation of a pseudomembrane as in Group A. In this group there were five examples. The changes consisted of congestion and hemorrhage into the mucosa with necrosis of isolated portions of the mucous membrane, which necrotic portions might be exfoliated so as to form ulcerations on the surface. The necrotic areas and ulcerations were usually surrounded by a zone of inflammatory reaction. The submucosa occasionally showed cellular infiltration. The other coats were not affected. Group D contained 14 cases which showed microscopically but few discoverable lesions, beyond congestion and moderate hyperplasia of the lymphoid tissue and, in one case, of slight cellular infiltration of the submucosa. There was very little histological change. As far as the other organs were concerned there were no characteristic findings. The mesenteric nodes were usually somewhat enlarged, rarely markedly so. The lungs showed hypostatic congestion and small areas of bronchial pneumonia. The

liver was fatty in about the same percentage as in other infantile conditions. The spleen was as a rule unaffected unless some other infection was added. The kidneys showed cloudy swelling. Cultures from the organs did not show the Shiga bacillus. It is evident that the Shiga bacillus may produce a great variety of lesions and that with these lesions may be associated all grades and types of diarrheal disease as distinguished by clinical symptoms and pathological findings.

Bacterial Flora in Infantile Diarrhea, with Especial Reference to the Dysentery Bacillus.—Dr. Charles W. Duval read a short abstract on this work, which he and Mr. E. H. Schorer had done during the summer, in the laboratory of the College of Physicians and Surgeons. Seventy-nine cases of so-called "summer complaint" were examined, under which clinical title were included all types of the disease from mild diarrhea to severe ileocolitis. The stools were examined within ten to fifteen minutes after they were passed and to this fact was due a large amount of the success obtained in isolating the *Bacillus dysenteriæ*. The bacillus was present in greater or less numbers in every variety of intestinal disturbance, and also in normal stools from infants. Of the cases of summer diarrhea, 75, or 94 per cent., showed the dysentery bacillus. The character of the stools was no certain indication of the presence of the *Bacillus dysenteriæ*, though the organisms were most likely to be isolated from cases showing bloody mucus. Plates from the stools showed a few scattered colonies or almost pure cultures. Five of the cases examined showed bacilli of the types "Harris" and "Shiga;" or, in other words, those which ferment or do not ferment on mannite. In this same group of stools, the Bacillus "Y" of Hiss and Russell was also isolated. Five cases contained the two types. In three the fermenting type predominated in the proportion of eight to three; in two the non-fermenting was present in greater numbers. In 11 cases the bacillus was of the non-fermenting type, or true "Shiga." In 58 cases only the fermenting or "Harris" type could be found. In the identification of the colonies after they had been fished from the plates, the semi-solid medium of Hiss was found to be superior to glucose-agar, as it excluded motile organisms and showed gas production in a few hours. In plating the stools it was found wise to select those parts which contained mucus and to shake them up in physiological salt solution or bouillon; then to set them aside for a few minutes to allow the coarser particles to subside, and to use one or two loops of the suspension for each plate, being careful not to disturb the settled particles. This method gave, as a rule, 50 to 100 colonies per plate. Plates were incubated for from fourteen to eighteen hours and then every small pearl-gray colony was subcultured to the Hiss medium. The colonies resembling *Bacillus dysenteriæ* were marked with a wax pencil and the plates were kept at a low temperature for a week, daily observations being made for fresh colonies. If the bacillus was not obtained in the first or second fishing all marks were erased and every small colon-like colony was transferred to the semisolid medium. All tubes showing a cloud were disregarded. Those showing a growth only along the track of the needle were stirred with a platinum wire in order to bring out the bubbles of gas which had been formed. The cultures showing no gas production were tested for the agglutination reaction by suspending a few loops of the growth in the semisolid medium in physiological salt solution and adding a known serum of high agglutinating power. The identification of the bacillus by the agglutination reaction was not, however, wholly reliable as there are bacilli which react in high dilutions but which culturally do not correspond to the dysentery bacillus. The speaker laid great stress on the reaction in litmus milk observed over a period of weeks for the final identification of the organisms.

Results of the Bacteriological Examination of the Stools from Cases of Summer Diarrhea, with the Especial Object of Finding the Bacillus dysenteriæ.—Dr. Herman Schwartz read a paper on this subject. He took only those cases of typical summer complaint which were characterized by profuse watery stools with little or no mucus. He first examined the blood of 25 healthy infants for agglutination reactions with *Bacillus dysenteriæ* in dilutions of 1 to 10, 1 to 20 and 1 to 50. These, with one exception, 1 to 10, were all negative. The normal stools of three healthy, breast-fed and three healthy bottle-fed babies were then examined with negative results. The stools from 30 cases of the character as stated above were also studied.

Technic.—The stools were taken by means of double tubes; the anal region being disinfected, the larger caliber tube was inserted about one-half inch in the rectum; the second tube of smaller caliber and longer than the first, was inserted through this larger tube, well into the rectum and the mucous membrane of the latter irritated. This seemed to be the only feasible method of obtaining these watery stools. When macroscopical mucus was present the fluid stool was put into a Petri dish and the mucus fished out and put into bouillon. Otherwise, a few c.c. of this fluid was put into bouillon and then in 13 cases agar plates in the ordinary way made. In the remaining 17, the method used by Dr. Duval was used. In all the 30 cases the results were negative. The blood of these cases was also examined for agglutination reactions (1 to 10—1 to 20—and 1 to 50), with negative results.

Conclusions.—(1) The blood of healthy infants and children rarely contain agglutinins for the dysentery bacillus; (2) the normal stools of infants in the cases examined did not show the presence of these bacilli; (3) that in the cases of typical summer diarrhea with green, watery stools, these bacilli were not present, or if present, must be in exceedingly small numbers; (4) the serum from these cases of summer diarrhea showed no agglutinins for the dysentery bacillus; (5) from the results of these observations, it would seem that these bacilli are not usually a factor in this class of summer diarrhea.

Diarrhea in Infants.—Dr. Martha Wollstein read a paper in which she described the results of the study, during the three summer months, of 62 cases of diarrhea in infants from two months to two years old, the stools of which had been examined for the Shiga bacillus in the laboratory of the Babies' Hospital. Dr. Grace Dewey had assisted in the work. The material had been obtained from the wards of the Babies' Hospital and of the Foundling Asylum. Of the 62 cases, 47, or 78 per cent., were positive. At the Babies' Hospital the mortality rate was 55 per cent. of the positive cases and at the Foundling Hospital 78 per cent. From stools containing much mucus, with or without blood, the Shiga bacillus was isolated quite readily in most cases. Stools with little mucus and no blood often necessitated fishing of very large numbers of colonies on successive days before any *Bacillus dysenteriæ* could be found. In every instance it was the acid of mannite-fermenting variety of *Bacillus dysenteriæ* which was encountered in this series.

Gastro-intestinal Disturbance in Infants and Children.—Dr. Louise Cordes reported the results of an examination of the stools of 51 patients of gastro-intestinal disturbances in infants and children conducted in

the laboratory of the New York Infirmary for Women and Children, in order to determine the presence or absence of the *Bacillus dysenteriæ*. The material was obtained from unselected cases; even those showing the mildest symptoms were examined. It was, in a good many cases, obtained fresh and plated at once. The *Bacillus dysenteriæ* was found in the stools of 26 cases, two of which were five and ten years old, respectively. In 25 of the stools the acid mannite type of the *Bacillus dysenteriæ* was found. In one the alkaline mannite type. Agglutination as high as 1 to 3,000 and 1 to 3,500 was obtained with the bacillus of the acid type from six cases. The same organisms showed an agglutination with the Shiga anti-dysenteric serum in from 1 to 200 to 1 to 500. The bacillus of the alkaline mannite type gave a positive reaction with the Shiga anti-dysenteric serum in a dilution of 1 to 7,500. With the Harris anti-dysenteric serum a fair agglutination was obtained at 1 to 2,000. The blood of 45 of the patients was tested with the Harris and Shiga dysentery bacillus in dilutions of 1 to 40 or 1 to 50. In ten a positive reaction was obtained.

Etiology of Dysentery and Summer Diarrhea.—Dr. William H. Park reported the results of investigations carried out by himself and Dr. Katharine R. Collins and Dr. Mary E. Goodwin upon the etiology of dysentery and summer diarrhea at the Research Laboratory, the work having been carried on so much in common that a single joint report was made, as follows: In general the results agreed with those reported by Drs. Wollstein and Cordes and differ somewhat from those of Dr. Duval. They had not found the Shiga type of bacilli at all in the ordinary summer diarrheas. Especial attention was paid to the agglutination of the two groups of dysentery bacilli. The agglutination test for the identification of the dysentery bacilli is one to be carried out only with the greatest care. The test properly performed is delicate and reliable, but when carried out with insufficient precautions is misleading. It has been known for some time that the blood of animals before immunization, possessed in moderate amount substances which agglutinate many bacteria. An agglutination of bacteria must, therefore, take place in high dilution of serum before it can be considered a specific reaction. From results obtained in the Research Laboratory Dr. Park considered that even this requirement was insufficient for testing dysentery bacilli. It was found before any inoculations had been made, that the blood serum of certain horses agglutinated, even in such high dilutions as 1 to 1,000, both the bacilli having the characteristics of the true dysentery bacillus of Shiga, and those having the characteristics of the mannite-fermenting class of Kruse, Flexner and Duval. This applied to a less extent to the serum of grown goats and even in a very slight degree to the serum of rabbits. It has happened in some instances that after repeated injections with cultures of one of the varieties of the dysentery bacilli, that the animal's blood agglutinated the variety of bacilli not used in immunization in as high or even higher dilutions than it did the variety injected. It was also found that a serum drawn from a horse which had been immunized by repeated injections of the dysentery bacillus received from Shiga, agglutinated this bacillus in dilutions of 1 to 500. The same serum, however, agglutinated the mannite-fermenting bacillus in dilutions of 1 to 1,000. The serum from another horse which had received injections of the mannite-fermenting bacillus, agglutinated this bacillus in dilutions of 1 to 1,000; but also agglutinated the Shiga bacillus in dilutions of 1 to 500. These two different varieties of bacilli would be judged by these reactions to be much alike in their affinities. Indeed, Shiga and Flexner seem to have made this mistake. Duval and Bassett certainly fell into this error, when they announced in the fall of 1902, that the mannite-fermenting type from the Baltimore diarrhea cases and the Shiga type had identical agglutination characteristics. These varieties are now known to differ completely in this respect. Young animals before immunization were found to be wholly or comparatively free from bacterial agglutinins, and in them we were able to produce an almost pure development of specific agglutinins. A goat six weeks old was found to possess before treatment no appreciable bacterial-agglutinating substances in its blood. After four injections of a culture of Shiga dysentery bacilli, its blood in dilutions of 1 to 500 agglutinated Shiga bacilli, but only in dilutions of 1 to 10 the mannite-fermenting variety. A rabbit, whose blood was negative before immunization, after six injections of this bacillus agglutinated the mannite-fermenting bacillus in dilutions up to 1 to 5,000. The Shiga bacillus was agglutinated only in dilutions of 1 to 20. The slight development of substances which agglutinated the mannite fermenting type during the process of immunization to the Shiga bacillus cannot be considered as showing any affinity between the Shiga type and the fermenting type, as about the same increase was found in animals injected with nutrient bouillon and other substances. It seems that the general employment of immunized horse's serum for differentiating varieties of dysentery and colon bacilli is a mistake. The true dysentery bacilli of Shiga were found in ten cases of characteristic dysentery ocurring in different parts of Mount Vernon and Tuckahoe. These towns are situated just north of New York City. The bacilli were also found in a serious case occurring in the Coney Island district of Brooklyn. The mannite-fermenting bacilli were found in about one-half the cases in the Mount Vernon epidemic, in five cases among workmen on Riker's Island, in two cases at Orange, in one case at Coney Island, and in three cases in New York City. All the above cases exhibited characteristic symptoms of dysentery and differed in no way from cases where the true Shiga bacilli were obtained. In no characteristic case of acute dysentery where suitable material for examination was obtained did they fail to find either the Shiga or the mannite-fermenting type of dysentery bacilli. Besides the characteristic cases of dysentery in which, as a rule, some history of infection was obtained, a large number of cases of summer diarrhea were met with in which excessive mucus, with or without traces of blood, occurred in the stools. In the majority of these cases the mannite-fermenting type of dysentery bacilli were found, although at times in very small numbers. In none of these were the Shiga bacilli discovered. In cases of cholera infantum, no dysentery bacilli of either type were met with. They were also not obtained from the stools of cases of subacute diarrhea in institutions where no cases of the dysentery type existed. The blood from cholera infantum and simple diarrhea cases did not clump any of the dysentery bacilli in the author's collection in dilutions higher than 1 to 10. The Shiga type of bacilli obtained from three different localities were found to agree closely in cultural characteristics, in their agglutination, and in their sensitiveness to a specific bactericidal serum with the cultures of the same type obtained from Shiga (Japan), Duval (New Haven), and Wollstein (New York City). The mannite-fermenting bacilli from the characteristic cases of dysentery and from the cases of summer diarrhea agree in most respects with each other and with the cultures obtained by Flexner in Manila and by Duval in Baltimore. They differ quantitatively and possibly also qualitatively in their reactions to the specific agglutinins ad bactericidal substaces produced in animals after injection of different cultures. From the Shiga bacilli

they differed wholly in their reaction to specific agglutinins and bactericidal substances. The writers believe that it would simplify matters to designate the bacilli identified by Shiga as dysentery bacilli, and the mannite-fermenting, indol-producing bacilli as paradysentery bacilli. The Shiga variety is found rarely, except in the characteristic cases of dysentery or in milder cases associated with them, while the mannite-indol type is found in a moderate number of characteristic cases, but most often in the irregular mucous diarrheas of summer. The relationship between these two groups of bacilli is very similar to that between the typhoid bacillus and the paratyphoid bacillus.

Dr. Park, in the discussion, asked Dr. Duval if he did not think that a serum, such as the immunized horse serum, which frequently agglutinated both types of dysentery bacilli in high dilutions, as well as other bacteria, was dangerous to use for purposes of accurate identification.

Dr. Duval replied that Dr. Park evidently misunderstood his paper; that he identified the organisms culturally and then tested every culture with the sera Shiga and Harris. All his isolations were agglutinated by dysentery serum. The serum he used was that prepared at Philadelphia by Dr. Gay. The horse serum used, agglutinated in dilutions of 1 to 1,000 or more. The main point was to determine first the cultural features, then try the agglutination reaction. If Widal is made first, obtaining positive reaction with the horse serum in 1 to 50, 1 to 200 or 1 to 500, the bacilli cannot be identified as dysentery unless followed out over a period of several days, with special reference to litmus milk, to identify them by their cultural features.

Dr. Libman said that the work reported indicated that the bacilli were found mainly in the cases with mucus or mucus and blood, and that it seemed that every loose stool with mucus was accompanied by the organisms in question. Such a condition of affairs—that is, a constant etiological factor for a pathological secretion—was unknown elsewhere in the body. So that the question arose whether the mucus was not a favorable medium for the growth of organisms which might be present normally, in at least some of the cases. He was aware that the organisms had not been found in normal stools; but a crucial test had not been made. The contents of different parts of the bowel should have been examined in children that had died of non-diarrheal diseases. While he did not wish to doubt the relationship of the organisms in question to diarrheal diseases, a doubt would remain until such studies as he suggested were made. It was possible that organisms which existed normally in the upper part of the bowel might be found in the stools in diseased conditions. Tissier had shown that a dose of calomel was enough to produce a stool full of streptococci in cases where none or very few had been present before. He said he had, several years ago, found in two cases of cholecystitis, bacilli corresponding culturally to the dysentery bacilli. Dr. Libman believed that one could not say that a bacillus which when isolated did not agglutinate with a specific serum was not a dysentery bacillus. One ought to make several tests; for it might be possible that such an organism might react after it had been cultivated outside of the body. He and others had had such experience with the typhoid bacillus. Dr. Libman asked Dr. Duval what his experience had been with the thread reaction; whether he had found it more or less specific than clump reactions.

Dr. Duval replied that his bacillus did not differ from the true Shiga type, except fermenting in mannite. The kind of reaction (end to end or tight clump) depended on the media and serum employed. Sometimes a fresh Shiga culture would give an end-to-end reaction and sometimes the Harris culture would give it. No hard and fast rule could be laid down.

Dr. Park said that in most of the diarrheas with profuse serous discharge bacteria were very abundant. In a dysenteric stool from a man working on Riker's Island, which was almost pure blood, very few bacteria developed.

Dr. S. J. Meltzer wanted to know whether watery stools had ever been examined for their bactericidal effect. Such stools, being transudates from the blood might possess acquired bactericidal power, specific for the organism which is the primary cause of the dysentery. Hence the absence of just this group of bacteria in the watery stools.

Dr. P. H. Hiss said that he had noticed a tendency in the papers read that evening and during the discussion to refer to the dysentery bacilli as of "acid" and "alkali" types, and to speak of "acid" and "alkalin" dysenteries. He thought that it was not scientifically correct to divide these organisms into "acid" and "alkali" types, as both of these types produced acid freely if in the presence of a suitable sugar. So far as he knew, in the presence of proteid and nitrogenous food alone, one of these types would give rise to as much or as little, alkali as the other. It did not, therefore, seem to him correct to speak of an "alkali" producing type, simply because that type did not ferment as many kinds of carbohydrates as the so-called "acid" type. Dr. Park had suggested the name "para-dysentery" for the group composing the active fermenters or "acid" type, in order to distinguish it from the true *Bacillus dysenteriæ* of Shiga. These active fermenters had already been shown to be divisible into two fairly distinct types not only by their fermentation reactions, but by differences in agglutination. In view of these facts and our as yet really limited knowledge of these organisms, and their relation to dysenteries and diarrheas, it seemed early to attempt to name them or at least to mass them indiscriminately under one group name. At present we knew only something of their action on carbohydrates, practically nothing of their action on proteid or other nitrogenous food materials, and the further study which was necessary might lead us to a different conception of the members of the group.

Dr. Park said that prefixing the term "para-" simply separated that group from the Shiga variety, and did not necessarily limit the mannite-fermenting bacilli to a definite group, but left that to the future to decide. Most of the bacilli so far obtained were, however, in most characteristics, similar. Some of the German bacteriologists had used the term "pseudo-dysentery" for this group, but this was misleading. He agreed fully with Dr. Hiss, but said that the terms "acid" and "alkali" were simply terms of convenience, and referred to the appearance of the differentiating litmus mannite medium. He would like to know how Dr. Hiss would designate these organisms.

Dr. Hiss said that he considered it a mistake to adopt short and convenient terms when they were not scientifically correct, and that it would be better to speak of these organisms as mannite fermenters and non-mannite fermenters.

Dr. Herman Schwartz asked Dr. Duval whether he found bacilli in watery stools where no blood or mucus was present, or in true summer diarrhea, and was answered affirmatively.

Dr. Park said that the term "dysentery" was a distinctly clinical term. It referred to an acute infectious disease lasting from one to four weeks, having the distinguishing symptoms of abdominal pain, tenesmus, and frequent stools of blood and mucus with more or less feces and serous fluid. These cases were rarely seen in New York City, but occurred by hundreds in

country towns. It was impossible to examine the mucous membrane of the intestines in these cases during life. From the location of the pain and the character of the stools it was, however, possible to determine pretty accurately the extent of colon and small intestine involved and the character of the inflammation.

Dr. L. Emmett Holt did not think we were much helped in the classification of intestinal diseases by the researches reported. For instance, such cases of colitis as were found by autopsy to have large quantities of pseudomembrane had always been included in the group, dysentery, but were frequently without blood and mucus as clinical symptoms. To exclude them from the classification on this basis seemed irrational.

Dr. Park said that the uncomplicated cases of dysentery outside of hospitals usually recovered in this climate, and when fatal an autopsy could rarely be obtained. The autopsy findings in some atypical hospital cases due to the mannite-fermenting type in which extensive membrane had been present, had been carefully examined by Dr. Howland, whose report had just been read. It was very difficult to determine in these cases what portion of the lesions should be ascribed to the poison of the dysentery bacillus. In these cases no true Shiga dysentery bacilli had been found.

He said that it was a recognized fact that different micro-organisms produced inflammations resembling each other in many respects. Thus, we had syphilitic inflammations of the pharyngeal mucous membrane and also lesions due to Vincent's bacillus, which closely resembled in appearance the lesions of diphtheria. We also had the slighter lesions due to the streptococci. Notwithstanding these facts no one doubted the value of recognizing the most important and frequent infection of this region as diphtheria. The same reasons existed for the term "acute dysentery."

Dr. George P. Biggs said that the term "dysentery" referred simply to a group of clinical symptoms and had no place in pathology.

Dr. David Bovaird said that there were three distinct points of interest in the discussion: (1) He could not tell from pathological lesions which cases were Shiga bacillus infections or were associated with other bacilli. (2) He could not tell from clinical picture which cases were produced by Shiga bacillus and which were not. (3) Nor was the agglutination test alone reliable evidence as to which cases are produced by the Shiga bacilli. Practical workers had no other means than the bacteriological for recognizing these cases. The physician must wait for further information from bacteriologists before making definite distinctions either as to the bacteriological association of these cases, or to the prospect of treatment with specific serum.

Dr. Park said he could judge in what cases dysentery bacilli would be found, as well as he could where typhoid bacilli or diphtheria bacilli would be met with. They would always be found readily in cases of epidemic dysentery and usually wherever acute diarrhea was accompanied by mucus and blood. In cholera infantum they would not be found.

Dr. Schwartz thought it was going too far to say that summer diarrhea was due to the dysentery bacillus. When blood or mucus preponderated the bacilli were found without difficulty; but in commoner cases of summer diarrhea, even if a few colonies were found, one could not say that the dysentery bacillus was the cause of the watery stools.

Dr. Duval wanted to know if with the bacilli in one of the eight colonies from such a case there was reaction with that patient's blood 1 to 50, 1 to 500, 1 to 1,000, and all other organisms in the intestinal tract were not agglutinated, what importance would Dr. Schwartz attach to that finding.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

Stated Meeting, held November 20, 1903.

The President, T. Halsted Myers, M.D., in the Chair.

Dislocation of the Humerus Complicating Obstetrical Paralysis.—Dr. R. Whitman presented two cases illustrating the treatment of this affection. The method which he had employed was similar to that of the Lorenz reduction at the hip-joint. This was preliminary forcible manipulation to stretch the contracted parts and reduction by overextension of the elevated arm which was then slowly forced downward to the side of the body and fixed by means of a plaster bandage. This was retained for several weeks or months and on its removal manipulation and muscle training were if possible begun. In some instances it might not be possible to reduce the displacement at the first attempt. Cases of this character were sometimes classed as true congenital displacement or misplacement of the humerus, but they were in most instances secondary subluxations induced by the habitual attitude of abduction and pronation characteristic of obstetrical paralysis. In certain cases repair of the injury to the nerve trunks had taken place and yet the function was disabled because of the subluxation of the head of the humerus backward which made supination of the forearm impossible. In such instances the correction of deformity might accomplish a practical cure. In the majority of cases of this character the paralysis was irremediable, yet even in this class the reduction of the displacement improved the attitude and function of the arm. The first case was that of a girl, eight years of age, operated upon three months before. The reduction was successful, the attitude was normal, there was a fair range of motion in the joint and apparently no paralysis of the muscles. In this case functional cure was probable. The second case was that of a boy, eleven years of age. The extent of the original injury to the nerves was indicated by the atrophy and loss of growth of the extremity. In this case reduction was difficult, requiring several sittings. Now, about one year after the operation, the head of the humerus appeared to be firmly fixed in its proper position. Although there was but little power of voluntary motion in the joint, the appearance and the function of the limb had been considerably improved by the reduction of the displacement.

Coxa Vara.—Dr. Whitman also presented a case illustrating the operative treatment of coxa vara. The patient was a girl, ten years of age, who had limped for two years and had recently complained of much pain and discomfort. The treatment consisted in the removal of a sufficient wedge of bone from the base of the trochanter to permit the restoration of the normal angle of the femoral neck. A thin layer of bone at the extremity of the wedge formed a hinge, the two opposing surfaces being brought into contact by abducting the limb. In this maneuver the trochanter being fixed by contact with the upper border of the acetabulum further abduction of the shaft closed the wedge-shaped opening. In this attitude the limb was fixed by means of a plaster bandage until repair was complete. In the patient presented but slight trace of the former disability was evident although the operation had been performed in September, the bandage having been removed about three weeks before this meeting.

Dr. V. P. Gibney in the discussion of Dr. Whitman's second case, said that he remembered seeing the operation. He thought at the time, that the stretching had not been done sufficiently well to get the arm far enough back to make the re-position and reduction of the arm where it belonged, absolutely sure. The boy had been

kept at the hospital for a long time. After the removal of the plaster it seemed to the speaker, he had had a little better range of motion than at present. He said all were familiar with the cases presented by the late Dr. Phelps. The open method had been adopted, but he could not quite see how a perfect result could be obtained until the parts could be held in better position and for a longer time than by the present treatment. Dr. Gibney thought Dr. Whitman was working in the right direction, and that by and by a perfect method of treatment for this deformity would be evolved.

Dr. Whitman said that this case was complicated with paralysis and could not be discussed as a simple dislocation.

Dr. Gibney said such cases were called obstetrical paralyses. Later on, other parts were involved. In the case under discussion the head of the bone could be distinctly felt back of the shoulder joint. It was simply a question of terms; many called the condition congenital dislocation. Whether the paralysis caused the dislocation, he did not know. He was as yet unconvinced that it is a true paralysis.

Dr. H. L. Taylor said he judged that these affections were secondary to obstetrical palsy, and should be reduced by a system analogous to that employed in congenital hip dislocation. In this case the shoulder seemed to be in good position. There was subluxation of the end of the clavicle, which was not important, though quite prominent. There is limited use, but, as Dr. Whitman had said, it must be remembered that the arms were more or less palsied, and the getting of the head of the humerus into its socket and keeping it there was certainly an improvement in the child's condition, and an improvement over the cutting operation for getting the arm into position.

Dr. Lesynsky said that he had been very much interested in the case several years ago when he had seen a number of these children. The condition was then ascribed to injury to the brachial plexus, fifth and sixth roots, paralysis terminating in luxation of the shoulder-joint. If the muscles did not undergo regeneration under treatment or spontaneously, there was permanent disability. The speaker was glad to see such good results obtained by manipulation without any other operative interference.

Dr. L. Pierce Clark said that he was very sorry that he could not know more definitely about the cause of this condition, particularly in regard to birth. He thought that these conditions figured as obstetrical palsy due to lesion by stretching the fifth and sixth cervical roots, although there often was injury to other roots. He had palpated the plexus in both cases. He could detect the site of lesion in both. He thought the range of paralysis in the boy was greater in the brachial plexus. He thought other roots could be found damaged far down in the plexus behind the clavicle. In obstetrical palsies the deltoid suffered most because it was most completely supplied by the fifth and sixth cervical roots; then the biceps and supinator brevis. Subluxation of the shoulder was secondary to the paralysis; the atrophy in the deltoid corresponding to the atrophy in the shoulder joint. It is a painful condition, and while operation may enable the muscle to work at much better leverage, nerve section and suture must be done. Kennedy had done the most successful operations of this character recently. The speaker had, during the past year, looked up a series of cases on which Dr. Alfred Taylor had been doing nerve section and suture. The cases had been doing all that could be expected, but much time was required for reparative processes, and they were not ready for presentation, but would be in four or five months. In such operative work as that presented by Dr. Whitman, this operation would not influence the pronation of the hand, because that was done by the supinator brevis. This attitude of marked internal rotation was present, not because the pronators were weak, but because the external rotators had been paralyzed. As the condition gradually improved, the elbow came down to the side and contractions took place. Last in the process was pronation of the hand. He had never seen cases of obstetrical paralysis in which this lesion had been marked, in which there had been entire recovery of supination of the hand under any form of treatment. He said that massage and passive movements were disregarded by neurologists, as the patients never carried out the movements under their own volition. After operation, a series of educational principles had to be carried out, and afterward cerebral training was given. Representations of movements must take their position in the brain. The brain, and not the muscles, must be educated. The speaker thought Kennedy's brachial plexus operations more successful than others, because he applied the cerebral education principle.

The chairman, Dr. Myers, wished to know in how severe cases of these paralyses Dr. Whitman applied reduction. Was it not possible, in some cases, to produce immobilization in this way at the shoulder joint, and so secure more motion of the arm through the less paralyzed muscles acting on the scapula?

Dr. Whitman said he had studied the Hospital Reports carefully in thirty or more cases of obstetrical palsy, and had seen the patients come in, all having the well-known attitude belonging to this condition. There was at first no subluxation present at all; it was the effect of the continued pronation and abduction. For that reason, Dr. Whitman thought passive motions of great importance in order to prevent such conditions as he had shown. Whether there was paralysis or not he thought it better to have the head of the bone in the normal position. Then there was power to supinate the arm. In the case of the little girl, Dr. Whitman thought there would be recovery of function, because the injury to the brachial plexus had been slight, but in the other case there would never be recovery, as the injury had been great, as shown by the atrophy of the muscles. There was complete anchylosis of the shoulder joint. It was better with complete anchylosis to have the head of the bone in its proper place, which was all he had attempted to show. In former times this bad attitude had been allowed to persist, now it was remedied. It was better to do this forcible operation in one, two or three sittings, thoroughly stretching the parts, than to make a section posteriorly without stretching. Whether or not they could be successfully replaced, and whether they would stay in place, he did not know. He did not present them as favorable cases. Thus far the bone had remained in position, and function was very decidedly improved.

Dr. Gibney asked Dr. Whitman whether he did not think it would be better to do an excision of the head of the bone in the boy's case, in view of the importance of having it in its proper place, thus giving the patient a more flexible joint.

Dr. Whitman replied that it seemed to him that the atrophy of the scapula and shoulder muscles was very great. The arm was considerably shorter than the other side. He thought excision would be of little use if there were not sufficient muscle to move the arm about. It was a difficult case at the time of operation, and he was obliged to attempt to replace the bone in two sittings. Had been perfectly contented to have complete anchylosis because the attitude was much better. The boy now had partial supination, he had none before. The

boy had had no treatment after the operation, whatever, except what the mother had been able to give him, in the way of massage, etc. He thought in the reduction of all deformity of long-standing, the operator should not attempt to do what was required in less than two or three sittings.

Dr. V. P. Gibney said that he wished to report the case of a boy, ten years of age, with marked flexion deformity and subluxation of the head of the tibia, presenting a long cicatrix below the patella. He thought it, on first sight, a case of exsection of the joint in early life, and the usual recurrence of deformity that takes place in those cases. He wished it, however, placed on record as malarial synovitis of the knee, or synovitis occurring during malarial attacks, and wanted to bring up the question as to whether it was osteitis or pure malarial synovitis. Dr. Whitman had operated on the boy last Tuesday, doing osteotomy above the condyles. The leg was now quite straight. Dr. Gibney showed a radiograph of the limb and wished to call attention to the curving of the lower end of the femur which takes place in tuberculous lesions of the bone, and have it compared with the sound limb. The history of the case, in brief, was as follows: Boy, ten years of age; entered Bellevue November 22, 1900. Family history negative, save for malaria, which attacked all the members of the family just before the boy's admission to the hospital. Plasmodium had been found in the blood. At the end of November, 1900, the boy began to have chills followed by fever and sweating. This occurred every other day. He would have twenty chills, accompanied by nausea, vomiting and diarrhœa. Always severe frontal headache. No symptoms. Looked well nourished but slightly anæmic. Heart normal, slightly irregular. Temperature 102.2 to 103° F. On December 7 was in good condition and was discharged. On December 9 was readmitted to hospital, suffering from relapse. Arsenic was given. December 11, Warburg's tincture was given. Temperature dropped. Tenderness in right knee and elbow. There joints swollen and stiff. Soda bicarbonate and salicin were given. December 14, very painful. Salicin continued. December 20, condition unchanged. Tenderness most marked at outer aspect of tibia. Inguinal glands swollen. Stools numerous, indication of colitis, etc. January 1, 1901. Joint less tender, stools less numerous. No blood, no mucus. January 8, joint still painful. Marked contraction of the leg. Massage and passive motion given daily. Stools fewer, and more normal in character. January 11, complained of pain in joint. January 18, transferred to surgical division. January 20, joint opened, and cartilage found diseased. Scraped away completely, bones found intact. The quadriceps extensor was cut out to get the patella out of the way. Suture by chromicized gut. Skin suture with silk. Plaster of Paris applied from hip to toes. January 31, patient in good condition.

Specimen found to be the seat of chronic inflammation. No tubercles. March 4, removed plaster. March 5, temperature 100° F. Plasmodium found. March 7, malarial chill 11 A.M., followed by fever 104.8° F. Sweat. Re-applied plaster. March 25, removed plaster, applied splint. Slight fever in knee-joint. April 5, goes about ward pretty well. Runs with slight limp. May 10, discharged. Admitted to Hospital for Ruptured and Crippled November 5, 1903, with deformity described by Dr. Gibney, and shown by radiograph.

Knock-knee. Dr. Gibney also described this case. The patient was a large Swedish woman, thirty-two years of age. The knock-knee was very marked. Very little history could be obtained. On the inner side of the knee what seemed to be a very hard mass appeared, not distinctly outlined. It was suggestive of osteosarcoma, but the diagnosis was not positive and an X-ray was taken. This showed a much elongated internal condyle, and cuneiform osteotomy was done and the limb was brought around in perfect position without difficulty.

Dr. Whitman said that he thought the bending of the lower extremity at the knee not uncommon in flexion deformity so often seen.

Dr. Taylor related the case of an Italian with obliquity of the pelvis. The man complained of backache, and on examination marked pelvic obliquity was found. Short legs were not uncommon but the trouble with this man was that one leg was longer than the other, which was normal. The condition was due to an old disease of the tibia. One leg was one-half inch longer than the other.

Dr. Napier said that unfortunately the patient of whom he could speak was beyond presentation. The case was one he presented at the April meeting of the Section. A boy of fourteen years, who had lateral curvature with some rotation, beginning Pott's paraplegia. After the [illegible] the boy was ordered to bed. At that [illegible] paralysis had somewhat increased. On Tuesday, April 21, a plaster jacket was applied in suspension. The paralysis had then extended along the legs, and was almost complete. There was nearly complete loss of control of bladder control and no movement of the bowels. Temperature normal. The boy was kept quiet. April 22, in the morning, nearly complete paralysis, loss of all power in the arms, very little sensation. Respiratory excursions, temperature normal. During the afternoon, the breathing became difficult. On April 23, at 1 o'clock, he died of paralysis, apparently, of respiration. Dr. Napier reached the house a short time after the boy died. He presumed the case was one of [illegible] poliomyelitis. He wondered whether the concussion of the bones might not have caused the spinal cord lesion, the rapid paralysis.

Impairment of Growth Due to Cerebral Lesion.—Dr. Whitman presented a young woman, seventeen years of age, [illegible] since birth. No instruments were used, but the birth was tedious. Injured arm three inches shorter and forearm one and three-fourths inches less in circumference than the other. Face and chest on injured side much smaller than the other side. Possibly a marked case of so-called birth palsy. If so, involvement came from fifth and sixth cervical because the muscles of the hand were not affected, the extensors more so than the flexors. Electrical reactions normal. Sensation normal. Case puzzling because of extreme failure of growth and the fact that reactions to electricity were normal. The paralysis was of the cerebellar or spastic type, rather than of the spinal type. Less normal. He agreed with Dr. Clark that it was the elevation of the shoulder that was of benefit in these cases.

Dr. Whitman, in the discussion, said in that case there was partial subluxation of the humerus. The patient could put her hands and with the head of the bone in a normal position, she would have the power of supination. In certain cases of obstetrical paralysis there [illegible] employed all of the arm muscles, it was found to be injury of the cords of the brachial plexus, [illegible] After were left with little power in the arm. He thought subluxation required treatment.

Dr. Clark said that some three weeks ago he saw Dr. Witmer's case, to decide upon the feasibility of operation. He noticed the marked facial asymmetry. Since then he has re-examined several other cases of Erb's palsy to see if the non-development of the face was uniformly present on the side of the arm lesion. He has found it present in all where the patient is suffi-

ciently old to give an asymmetry which might come from asymmetric growth. He explained this new condition in Erb's palsy upon the disuse theory: The patient in failing to use the paralyzed arm and shoulder fails also to give the normal impulse to growth in facial muscles and bone. The side of the face on the side of the lesion remains behind in normal growth. In comparing the symmetry of the two sides in unilateral palsy lesions, such as Erb's palsy, a hypertrophied standard is employed on the sound side, just as in anterior poliomyelitis and infantile cerebral hemiplegia, owing to the excess development of the sound side through extraordinary labor thrown upon that side. The close association of the cerebral areas of muscular movements for the face, arm and hand in the motor region of the brain accounts for the face not developing when the arm remains paralyzed from birth—it is essentially a lack of associated voluntary muscular efforts. If on the contrary these efforts should be prolonged over a considerable period of time the face might not only show no non-development, but it might appear normal or even hypertrophied, as the partial palsy would serve to call out more persistent forced voluntary effort, thus calling into play the accessory associated movements in adjacent brain areas functionally allied, such as those for the face, when the arm is being used. During the past year Dr. Alfred Taylor has performed for Dr. Clark a series of nerve section and suture operations upon brachial plexus lesions of so-called Duchenne Erb or birth-palsy type, results of which will be reported later with observations upon the cause, pathology and treatment of the conditions. He can see no good or necessary reason to invoke two nerve lesions to account for these cases. The characteristic symptoms of Erb's palsy, together with palpation of the site of the lesion at Erb's point ought to make certain the diagnosis of birth palsy. Certainly he should not diagnose a cerebral lesion here, neither capsular nor surface hemorrhage, where there are no convulsions, no facial immobility, no spasm or spasticity of muscles, no incoordination nor spontaneous uncontrolled movements, and where the weakness is most pronounced in the deltoid and biceps and not distally as in cerebral palsy, also where there has been no marked increase in the reflex of the facial muscles nor in any of the paralyzed parts. Finally, it must be borne in mind that the labor difficulty causing the two affections is different. In birth palsy as in this case one has imperfect rotation of the trunk; the head is in extreme rotation, the shoulder is caught under the symphysis and the tension and stretching of the fifth and sixth cervical spinal roots results in an attempt to force the delivery by pulling on the head. In cerebral birth palsies the difficulty arises in the delivery of the head; it is compressed and the labor is markedly prolonged and much asphyxia results.

Dr. Witmer said the site of violence to the head might be remote from the location of the cerebral injury. He thought it was not unusual to find hemorrhage of the spinal cord in those cases of birth palsy.

Dr. Elliott exhibited a spinal column from a patient who had had the disease described by Marie. The patient was first seen by Dr. Elliott in 1897; was then examined under anesthesia for diagnosis. He was suffering from acute pain in the coxofemoral joint, with great hyperalgesia. Could not bear the weight of the bedclothes. The hip-joint was found to be anchylosed. The patient was a Russian, thirty-six years old, admitted to Presbyterian Hospital for pain in knee. Came to this country to avoid army service. Had been examined fifteen years previous, and found qualified as to size, for a soldier. On admission to the hospital support and extension were applied to the knee, and the symptoms subsided. In one and a half years he returned with pain in left coxofemoral joint which was anchylosed, gradually extending to the lower part of the spinal column, extending to dorsal and cervical regions, involving right hip, and subsequently the shoulders to a much less degree. Early in history he developed pulmonary tuberculosis. The bacilli were found, and that disease progressed hand in hand with the other. He died from tuberculosis about two months ago. The specimen was almost typical of that first described by Marie in *Revue de Médécine*, 1897. He described two cases almost simultaneously with Bernhardt, almost identical in involvement of the larger joints and the hip, all the small joints remaining intact. The curvature was gradual, the symptoms of pain and hyperalgesia subsided and the man then suffered only from his anchylosed position. Specimen exhibited and anchylosed parts pointed out.

Dr. Taylor, in the discussion, said that he had seen many specimens of stiff spines of this general character, but in those he had seen, the ossification was usually more marked on the anterior ligament, and in the lateral bands rather than the median and often on one side more than the other. Cases of spinal stiffness due to ossification of ligaments or to osteo-arthritis were exceedingly common, but it was only recently that they had begun to be recognized. In Marie's cases the large joints were involved, but there might be osteo-arthritis of the spine not involving the large joints and there might be osteo-arthritis of the large joints without involving the spine. Sometimes the spine and large joints were affected in succession. Sometimes there was deformity, sometimes not. The result depended largely on the rapidity of the process. If ossification took place rapidly, deformity was not so likely to occur; if slowly, there was equal round-back on both sides, or lateral spinal curvatures also.

Dr. Elliott said in reply to Dr. Taylor's remarks, that in all cases he had seen described under this type the anterior ligaments had escaped, as in this case. There seemed to be two or three different types of stiff spines, and he thought the variety in which the anterior ligaments were involved, was the stiff spine of ordinary arthritis deformans, where not only the large, but small joints were involved, and there was throwing out of deposit. Here there was no such tendency.

JOHNS HOPKINS MEDICAL SOCIETY.

Stated Meeting, held November 16, 1903.

Demonstration of Medical Cases.—Dr. Osler introduced the first patient, who was a man with aneurism causing a protruding tumor in the neck. There was a luetic, but no alcoholic history. The onset occurred two years ago, with pain in the shoulder, swelling of the feet and gradual development of the usual symptoms. Distal ligation of the right carotid was done and the tumor immediately increased in size—a feature quite unique in medical literature. The second case was a woman who showed peculiar mottling of the back and hands. The disease appeared after a mental shock, began with pain and numbness in the foot and was characterized by areas of local cyanosis alternating with livid spots.

Case of Generalized Neuritis from Lead.—This was Dr. Thomas' subject. The patient, a man of forty-six years, gave a marked alcoholic history, but the definite onset of his illness had occurred about two and a half weeks after entering an enamel works. There was marked delirium at onset, increasing weakness and some pain in right shoulder. Distinct blue lines in the gums, complete paralysis below the shoulder, ab-

sence of reflexes, slight dulness of sensation at the periphery, some muscle tenderness, granular degeneration of the red blood corpuscles and an irregular temperature were the features of the case. General lead palsy is a rare condition, only about 12 cases having been reported in the literature.

Dr. Hurd said that in lead paralysis the muscles most used are the ones most affected. In this patient alcohol cannot be eliminated as an etiological factor.

Case of Blastomycetic Dermatitis.—This subject was introduced by Dr. Gilchrist, who said that the disease began seven months ago as a pimple on the right wrist. This changed to a nodule, broke down and formed a papilloma. Later, lesions appeared on the thumb, thigh and face. Pus squeezed from the lesion gave a pure culture of the blastomycelium. This disease, of which there are about 50 cases in the American literature, must be diagnosed from tuberculosis and lues. The clinical features, with a microscopic examination of the pus, make the distinction possible. Treatment consists of potassium iodide internally, curettage and the use of the X-ray.

Metabolism in Pregnancy.—Dr. Slemons read this paper, and reported the results of studies made on four women whose metabolism was followed for about thirty-nine days. The diet was carefully regulated and weighed; all the excreta (including urine, lochia and milk) were carefuly measured, and daily estimates were made of the amount of urine excreted and the total nitrogen and ammonia output. The series showed a definite diuresis just before and just after delivery. All the cases showed a tendency of the mother to store nitrogen during pregnancy and the patient who bore live twins emphasized this tendency. The series also showed that during pregnancy there is a tendency for storing up ingested fluid. The ammonia excretion shows definitely that a fetus in utero causes changes in the mother's metabolism. It drops to normal after delivery and tends to become normal when the fetus dies in the womb. Relative suppression of renal activity explains the changes in the amount of excreted urine during and following labor. The diminution in nitrogen output is probably due to impairment of the kidney cells. The high ammonia output at the time of delivery cannot yet be explained. During the puerperium all the patients in Dr. Slemons' series showed a definite diuresis, except the one who bore dead twins. There was a rise in the nitrogen output, usually beginning about the second day of the puerperium and probably due to regressive changes in the mother. The ammonia fell gradually to normal. The series showed that metabolism tends to assume a non-pregnant type when the fetus dies in utero.

Dr. Emerson said that Dr. Slemons' report is particularly valuable because, in spite of the importance of an accurate knowledge of metabolism, no really good observations exist on which to base conclusions.

BOOK REVIEWS.

Manual of Operative Surgery. By Sir Frederick Treves, Bart., K.C.V.O., C.B., LL.D., A.R.C.S., Sergeant Surgeon in Ordinary to H.M. the King, etc. New Edition. Revised by the author and Jonathan Hutchinson, Jr., F.R.C.S., Surgeon to the London Hospital, etc. In two volumes. Vol. I. Lea Brothers & Co., Philadelphia and New York.

The appearance of this well-known work in revised form will be gratifying to those who have learned to know and admire its previous edition. Considerable changes have occurred in surgical thought and action even in the brief time since this manual first appeared, and the revision has been sufficiently thoroughgoing to make it in its present shape a vital contribution to the literature of to-day. The author's choice of a coadjutor has been most happy, and the addition of Mr. Hutchinson's name to the title page has but increased the dignity and authority of the book.

This volume embraces the general principles of operative surgery, and the operations of general surgery, classed under the headings of the ligature of arteries, operations on nerves, amputations, operations on bones and joints and tenotomy. The two introductory chapters on "The Patient" and "The Operator" are masterpieces, and could be read with profit by every one practicing or expecting to practice the art of surgery. The *x* of the personal equation, the unknown quantity, which, in the patient so profoundly, and in the operator to an appreciable extent, modifies the results of even lesser operative procedures, is discussed with a breadth of knowledge and distinction of manner seldom equaled in modern medical writing. An interesting description of the operating room furniture, methods, etc., of the London Hospital, with numerous photographs, details the embodiment of aseptic principles, as now practised in the land that gave them birth. In this connection it is of interest to note that the author does not use gloves in routine work on clean cases. The remainder of the volume treats of the classical operations in a spirited and attractive manner that should make their study less irksome to students. The illustrations are, for the most part, clear and instructive, but we note with pain that a number of antique cuts, representing coat-sleeved and cuffed hands operating with wooden-handled scalpels, relics of a bygone era in the annals of surgery, have been allowed to remain, and we trust that a succeeding edition will see these anachronistic blemishes deleted from the pages of an otherwise perfect book.

Handbook of Obstetric Nursing, for Nurses, Students and Mothers. Comprising the Course of Instruction in Obstetric Nursing Given to the Pupils of the Training School for Nurses Connected with the Woman's Hospital of Philadelphia. By Anna M. Fullerton, M.D., formerly Obstetrician, Gynecologist and Surgeon to the Woman's Hospital of Philadelphia; Physician-in-Charge and Superintendent of its Nurse School, and Clinical Professor of Gynecology in the Woman's Medical College of Pennsylvania; Late Lecturer on Surgery and Operative Midwifery in the North India School of Medicine for Women. Sixth revised edition. Illustrated. P. Blakiston's Son & Co., Philadelphia.

This cleverly written little book has again been brought in line with obstetrical teaching of to-day, and is intended to instruct nurses in all the details which they are supposed to direct during pregnancy and the puerperal stage, and also covers the instruction in regard to the various emergencies which are so liable to occur in these cases while the physician is absent. It is a very handy edition and although not so complete and full in its information as those who are making this subject a special study might desire, yet it covers the subject sufficiently well for any ordinary obstetrical nurse and contains much information which a mother might read with pleasure and value to herself.

Adenomyome der Uterus. Von Thomas S. Cullen, Hülfsprofessor der Gynäkologie in der Johns Hopkins Universität. Baltimore, Md., Verlag von August Hirschwald, Berlin.

In this admirable "Arbeit," which is a part of the Festschrift dedicated to Orth on the twenty-fifth anni-

versary of his professorate, the author gives an excellent discussion of the anatomical and clinical features of a considerable number of tumors of this type which have come under his observation. They are divided into (1) adenomyomata, with relative preservation of the uterine form; (2) subperitoneal and intraligamentous adenomyomata, and (3) submucous adenomyomata. They form a distinct class of uterine growths, in which detached portions of practically normal uterine mucosa are found in the midst of areas of myomatous hyperplasia. They occur both in the body and cervix; the submucous variety being the least frequently observed. Attempts to establish an etiological relationship between conditions in the adnexa and this type of new growth have failed. The clinical history does not essentially differ from that of simple myoma and the physical examination also is usually not characteristic, except that a tendency to the early formation of adhesions is noted. The prognosis is good in so far that adenomyomata are not malignant growths, but a case is described in which carcinomatous degeneration of the glands of the mucosa incarcerated in a growth of this description occurred, and the two conditions not infrequently exist independently in the same uterus. The treatment consists in hysterectomy, as myomectomy is rendered impossible through the diffuse nature of the growth. The dissertation is a scholarly piece of work in harmony with the author's previous pathological studies and is representative of the work done in his university.

The Medical News Visiting List for 1904. Lea Brothers & Co., Philadelphia and New York.

Thirteen years of experience has resulted in the publication of a visiting list which comes as near meeting all the requirements of the physician's daily record and reference book as even the most exacting could demand. It is issued in four styles to suit the needs of all physicians: weekly (dated for 30 patients), monthly (undated for 120 patients per month); perpetual (undated, for 30 patients weekly per year) and 60 patients (undated for 60 patients weekly per year). It is a pocket-sized, wallet shaped book containing a large amount of professional information to which the practitioner so frequently finds it necessary to refer at the bedside. Weights, tables, instructions for examination of urine, incompatibles, extensive table of doses, directions for artificial respiration and a list of diseases and their remedies are among the many valuable things which are of easy access in this little book. It is well printed and bound in flexible leather. It offers a convenient notebook for easily and accurately keeping a physician's office accounts.

International Medical Annual. Under the general editorship of Clifford Allbutt, M.D., F.R.C.P.E. Vol. VII, Issued in May, 1904. Vol. VIII, Menstruation to Orbit. Longmans, Green & Co., New York.

The International Medical Annual we have had occasion to commend to our readers very highly, and in the two volumes here under consideration, we are pleased to note some more than usually interesting and profitable articles. Furthermore, the illustrations which were fewer in the earlier number, are now quite ample.

Of particular interest in the present number is the article on Tuberculosis of the Lungs, written by Dr. R. W. Philip. It is a clear, concise and yet comprehensive presentation of the story. Dr. D. C. Rees gives a singularly attractive discussion of Malaria, presenting a very complete summary of our modern knowledge concerning this disease.

The Physiology and Pathology of the Lymphatic System is well presented, the literature up to the time of the writing of the article being fully discussed. Diseases of the Mammary Gland are very fully discussed, as well as Maternal Impressions and Malingering. The short chapter on the History of Medicine is a very able presentation.

Vol. VIII contains a number of thorough articles; among these may be mentioned those on the Disorders of Menstruation, Mental Deficiency, Micro-organisms, Milk, Education of the Mind, Morphinomania, Diseases of Muscles, Nephritis, Neurasthenia, Occupation Neuroses and Obesity. This latter chapter, while short, is very practical.

Certainly this series is deserving of the highest commendation and the handiness of the volumes, good mechanical execution, as well as the intrinsic quality of the articles contributed, all combine to make this Encyclopedia a valuable one and one worthy of representation in every practitioner's library.

The American Illustrated Medical Dictionary. By W. A. Newman Dorland, A.M., M.D., editor of the "American Pocket Medical Dictionary." W. B. Saunders & Co., Philadelphia, New York and London.

As there are a number of medical dictionaries on the market it must be a source of gratification to the author and publisher that a third edition of Dorland's Medical Dictionary should be called for within a few years after its original publication. As in previous editions, the book is excellently printed and very practically bound in full flexible leather. The revision for the present edition led to the introduction of a large number of new terms, and there is evident a commendable purpose to keep the book thoroughly up-to-date. Medical lexicography, an almost uncultivated field twenty-five years ago, in America, has become in recent years one of the fruitful departments of our medical literature.

Clinical Pathology of the Blood. A Treatise on the General Principles and Special Applications of Hematology. By James Ewing, A.M., M.D., Professor of Pathology in Cornell University Medical College, New York City. Second Edition, Revised and Enlarged. Illustrated with 43 Engravings and 18 Colored Plates drawn by the author. Lea Brothers & Co., New York and Philadelphia.

Dr. Ewing's book has proved itself to be one of the most practical manuals on the important subject which it treats. In the consultation of the work there is the constant feeling that nothing is added for the sake of appearance nor for padding, but that all phases of modern hematology are treated from the standpoint of a practical pathologist, whose aim has been to help the clinician. A well-directed and determined effort has evidently been made to have the book thoroughly up to date, and for this purpose some paragraphs with regard to the bacteriology of the blood in pneumonia, sleeping sickness, granular degeneration of red cells, and leukanemia have been added while the book was going through the press. In order to bring the present edition up to the level of recent progress, references have been made to about four hundred articles or monographs. For those who are interested in special features of pathology, or who are looking up questions in detail, the very complete bibliography cannot fail to be of great service.

In general, it may be said that this is one of the recent American medical publications that gives assurance that at last we are in our medical text-books attaining the standard set for us by great European authorities.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 83. NEW YORK, SATURDAY, DECEMBER 26, 1903. No. 26.

ORIGINAL ARTICLES.

PREDISPOSITIONS TO TUBERCULOSIS.*

BY JOHN B. HUBER, A.M., M.D.,
OF NEW YORK.

THE Koch bacillus is, of course, the specific cause of tuberculosis. It will, however, be referred to but incidentally in this paper, which is upon predispositions to that disease. I shall divide the subject rather roughly into three parts. First I shall consider certain hereditary factors; then such factors as prove pernicious in the period between conception and birth; and finally postnatal predispositions.

It is pertinent to the trend of this paper to repeat the much-quoted statement that life is the continuous adjustment of internal relations to external relations. This very inadequate definition nevertheless emphasizes the position in which the organism is placed with regard to its environment. And it is in this broad aspect that I am about to consider the effects of external phenomena upon the economy with reference to a disease which, according to autopsy reports, leaves its imprint, in greater or less degree, upon more than 90 per cent. of humankind.

And I shall not be content to examine only into such predispositions to tuberculosis as may obtain in the time between birth and old age. I shall recognize the tremendous importance of prenatal influence. Indeed, the divisions of this subject which I have made are purely arbitrary; for at conception older cellular elements are but transmuted into a new cellular combination; nor is birth more than another step in a series of life processes.

It is not merely a fancy of the romancer, but a statement saturated with practical sense, that the past lies upon the present like a dead giant's body, so that it is as if a young giant were compelled to waste all his strength in carrying about the corpse of an old, an atavistic giant. We sleep in dead men's houses, bacillus-ridden as they are; we are sick of dead men's diseases; we live in dead men's lives; as these sentiments are taken from a dead man's book. And it is equally true that future generations must inevitably be affected by the disposition, physical or otherwise, of the lives of individuals in the present.

With regard to heredity in general it would seem that one may assume almost any position, and will be able to set forth many unquestionable facts in support of the stand he takes. In considering the heredity of tuberculosis we come upon a wide range of positions, from that of the transmission of the disease itself, to the declaration that tuberculous parents actually confer upon their offspring an immunity to the disease.

Since the demonstration of the Koch bacillus, and up to very recently, it has been generally agreed that only a tendency to the disease, a vulnerability, and not the disease itself, a soil predisposing the organism to tuberculosis, may be transmitted. These expressions are vague, from a scientific viewpoint, and it would be desirable if they could be made to express some definite condition.

There are certain signs by which this hereditary tendency to tuberculosis may be manifested. Chief among these is what I venture for the present to call the scrofulous temperament. The scrofulous child has a pallid skin and flabby flesh; there is often chronic blepharitis; phlyctenulæ are frequent; the nose is large and broad and acne-studded; there are nasopharyngeal adenoids and hypertrophied tonsils, so that these children are mouth-breathers, starved for oxygen. There are tedious inflammations of the mucous membranes—coryza, congested and unhealthy throats, and bronchitis exceedingly rebellious to treatment; there are persistent adenitis and periadenitis, the lymphatic glands becoming enlarged and remaining so. There is a sluggish, torpid metabolism. Altogether, there is evidence of a radical nutritive disturbance.

Besides struma, we find thoracic malformations, narrow chests, lacking also in depth, projecting shoulder-blades, and small respiratory muscles. There are emphysema and an evident capacity for breathing below the average. There is, again, defective development of the circulatory system, especially of the aorta; there are congenital heart-lesions, and the heart is small. There are anemia and chlorosis. Among other manifestations there are—slow teething and deficient ossification in children, infantilism, stunted growth, and defective genital development.

It is evident that among these signs of hereditary transmission some are of an anatomical sort, while others are functional in character. This is an important distinction from the viewpoint of practical therapeutics. For it is a well-defined law of heredity that functional rather than anatomical modifications are transmitted; at any rate the latter are consequent upon the former, the development of any organ being regulated by exercise of that organ.

Functional modifications may indeed be unaccompanied by anatomical stigmata; the former may be exaggerated through successive generations without giving a hint of their existence, until the stimulation of some exciting cause, as a traumatism or an intoxication, may bring them to light. Thus it is that many having seemingly vigorous frames nevertheless succumb to the on-

* Read before the New York Academy of Medicine, October 1, 1903.

set of the tubercle bacillus and its allied micro-organisms.

This fact should appeal to those who would claim, from an absence of demonstrable anatomical lesions, that there is no such thing as hereditary transmission. Tuberculous parents may not bequeath definite stigmata; nevertheless they often do impart a pernicious nutritive habit to their offspring. For instance, the latter may suffer because of insufficient respiratory activity. This would certainly occasion deficient oxygenation, so that there would result a lessened vigor of cell-regeneration and of connective-tissue formation, an imperfect metabolism, and the like—a condition of things pathological enough, yet in its incipiency at least non-microbic—a condition non-infectious, but cordially inviting infection.

Moreover, in examining these indications of a transmitted vulnerability to tuberculosis it is worthy of note that many of them are distinctive also of other affections in which heredity plays a part, such as insanity, alcoholism and syphilis. Insanity and alcoholism, non-microbic affections, are often correlated with tuberculosis; and there are not a few analogous features between the latter and syphilis. The conclusion then would seem warranted that in all such affections, tuberculosis as well as the others, there is a like degenerated condition of the organs and tissues, which makes them fruitful soil for microbic germination.

When we come to consider the period between conception and birth we find that specific congenital infection by the Koch bacillus undoubtedly exists. Tubercles containing the bacillus have repeatedly been found in the stillborn. The bacillus has been found in the seminal vesicles in the male, in the female tubes, and in other tissues concerned in reproduction; the bacillus and its toxins have been found in the semen of infected animals. And a conclusive simile may be adduced from undoubted congenital infection in syphilis, smallpox, glanders, cholera and pneumonia.

Still, these infections are comparatively rare; Frebelius has found tuberculous lesions in but 416 out of 16,580 autopsies upon sucklings; and Ballantyne holds that the placenta acts excellently as a sifter to protect the fetus from infection. What is probably much more frequent is a susceptibility to infection in the tissues of the embryo and fetus. Here the parental condition at the time of conception is an important consideration. Roger cites a case of parents of uncommon strength, who had three children. The firstborn and the youngest were very well constituted and had inherited the strength of their parents; the second, conceived at the time when his father was convalescent from pneumonia, was poorly developed, remained feeble, and at the age of twelve years contracted tuberculosis, from which he died. Similar cases will occur to every practitioner. Bodily or psychic disorders in the parents, fatigue, convalescence after a serious disease, advanced age at the time of conception, causes accidental, or perhaps so slight as to escape notice, or such as may be transitional in the parents, may induce a vicious nutrition, making the organism receptive to infection, tuberculous or otherwise.

During the embryonic period the cells become differentiated and the organs of the body are formed; during fetal life the organs thus formed increase in size and begin to take on their several functions. Throughout both these periods, but especially the former, the organism is most acutely sensitive to environmental impressions—to variations in oxygen supply, warmth, the chemical constitution of the maternal blood, uterine or placental diseases, and the like. When such influences are abnormal, it cannot be hoped that the tissues of the fetus will remain unaffected.

In coming to a consideration of postnatal predispositions, I will revert to certain aspects of struma—the pronounced sluggish metabolism; and the tendency to inflammation of mucous membranes and of lymph-glands, the respiratory membranes and the glands of the mesentery and the bronchi being marked sufferers.

Flick, Wright and others tell us that tuberculosis, a disease dependent beyond doubt upon the presence and the propagation of the Koch bacillus, is always, to begin with, a purely local affection. Tissues which have had their circulation disturbed by traumatism, vasomotor, functional or other disorders, become foci. The extension of the process then depends largely upon the spread of the bacillus from these diseased foci by means of the lymphatics and the blood-vessels. It is likely that the alimentary lymphatic channels are more active carriers than are those of the respiratory tract; and it is considered that the quality of the food ingested is of primary importance.

The idea that pulmonary tuberculosis comes about in the first instance through the inhalation of the Koch bacillus into the air-vesicles is considered erroneous. It is held that the bacillus cannot be inhaled because the function of the respiratory tract anatomically and physiologically is limited to the admission of gaseous substances only; that air is changed in the alveoli not by currents, but by the subtler influence of the law of the diffusion of gases. The main routes by which the lung tissues are invaded are then two: first by way of the alimentary canal, the course being the stomach, intestines, lacteals, thoracic duct, the vena cava, the right heart and the lung; the second route being by way of the bronchial glands to the thoracic duct, the vena cava, the right heart and finally the lung.

The pathologist has, in fact, found very little evidence of primary colonization of the Koch bacillus in the pulmonary parenchyma. There is abundant evidence of primary tuberculosis in the bronchial glands; but these are not, strictly speaking, parts of the lung parenchyma. However, in almost every part of the body, differing

in each individual according to his most vulnerable tissue, there is primary tuberculosis; in the lymphatics, serous and mucous membranes, skin, periosteum, in the intra-abdominal, intra-cranial and reproductive organs, in the nose, throat, ear, tonsils, mastoid and the eye. The place of deposit is not necessarily the point of entry of the parasite. There may be tissues which for many years have latently harbored colonies of bacilli, without setting up symptoms until the advent of some acute cause.

But how explain, then, the frequency of pulmonary tuberculosis, particularly in the apices? The first rib is frequently immovable, so that expansion is restricted; Schmorl has found a furrow running around the upper aspect of the apex, which he attributes to defective development of the first rib. He finds that the bronchial twigs which supply the neighboring parts of the lungs are often crooked, narrowed or otherwise deformed, so as to present a favorable situation for the persistence of catarrh in the mucous membrane. Then Esser points out that in children at least the inflamed bronchial glands often compress the bronchi and also the branches of the pulmonary artery, which supply the upper part of the lung. So that in the apical region there are lessened power of expansion, imperfect aeration and insufficient blood-supply. The pathology of cold is suggestive here; for tuberculosis frequently follows that condition. Cold will produce contraction of peripheral vessels, with pulmonary anemia, the blood being in most cases driven into the abdominal viscera. And anemic tissues present diminished resistance to infection, particularly when the Koch bacillus is the agent. Again the venous blood, bacillus-laden, from the thoracic duct, is first carried through the pulmonary circulation for oxidation before returning to the left heart. The lungs, therefore, bear the brunt of exposure to this infection, and act as a strainer to the general circulation.

The alimentary tract is, then, very intimately concerned in the spread of tuberculosis. It is to be emphasized here that in infants abdominal tuberculosis is more frequent than the pulmonary form; it is striking also that gastro-intestinal diseases are very prevalent in infancy and childhood, and that there is at this time much improper, or unsuitable, or artificial feeding. Carriere finds that in all cases of tuberculosis among children, 30 per cent. are of the lungs, 40 per cent. are of the peritoneum, and that tuberculous enteritis occurs in 20 per cent.; and declares, though too sweepingly, that the nutriment consumed furnishes the sole medium by which infection is accomplished. The germ is often taken in with the food, or from bacillus-laden things such as infants are in the habit of putting into their mouths. Tuberculous excreta from the upper air-passages are swallowed. In the stomach the germicidal properties of the gastric juice are encountered—an ineffectual safeguard, however. If digestion here is impaired or incomplete, the bacillus is passed intact into the intestines; here unassimilated material including the bacilli must occasion intestinal hyperemia. Under these conditions peristalsis mixes the undigested bacilli with the chyle. Then the lacteals and the lymphatics take them up and carry them into the mesenteric glands and the thoracic duct. Those which reach the mesenteric glands are likely to colonize and be carried into the thoracic duct, whence they will reach the pulmonary circulation by way of the vena cava.

It is a pleasure to refer here to Sajous' work on the "Ductless Glands," a patient, altruistic work extending over a period of fourteen years, the first five of which, as he tells us, were spent in futile gropings about. Although this work has received the hearty appreciation of his colleagues, his findings have yet to meet their acceptance. I set down here only certain of his views concerning tuberculosis. Vulnerability to infection, he declares, means insufficiency of the adrenal system and lowered oxidation; when this insufficiency obtains, the functional activity of the spleen and the pancreas and the production of trypsin are correspondingly reduced. The digestive process within the neutrophile leucocytes, which collect foodstuffs in the intestinal canal, is due to the action of trypsin; a deficient supply of proteolytic ferment therefore reduces the efficiency of this process. The protection thus afforded the general system is reduced in proportion; since undigested bacilli are pathogenic bacilli. The path which these leucocytes follow is the villi, the portal system, the right heart and the pulmonary circulation. Thus infection of the lung can occur through bacilli taken up by leucocytes in the intestinal canal.

Sajous further considers that relationship between the adrenal system and the alkalinity of the blood is an important feature in the pathology of pulmonary tuberculosis. In this disease, he declares, there is an insufficiency of alkaline salts; that during the pretuberculous and in the earlier stages of tuberculosis there almost always occurs a very marked loss of mineral salts, "causing one to wonder whether this demineralization might not be one of the mysterious conditions which create the soil for a rapid pullulation of the tubercle bacillus." Trypsin will not act in the absence of salts; and this ferment, according to Metchnikoff, is the active body which in the phagocytic leucocytes destroys the bacilli.

A faulty metabolism plays an enormous part in predisposing the tissues to tuberculosis. The presence in the body of nitrogenous matters in a decomposing or readily decomposable state affords an ideal pabulum for the nourishment and development of micro-organisms and their toxins; and such factors as unwholesome food, bad water and foul air will further an excess of these effete matters in the tissues. Ordinarily such material is limited to the amount which is continually being excreted in the ordinary waste of the body; and if the excretory organs all combine in normal action, this is drawn off from the blood currents

as fast as it is poured into them; so that the stream is kept clean. But if such decomposing matter be introduced abnormally from without, as in habitual infractions of hygienic laws, such as many who contract tuberculosis are addicted to; or if it be generated in abnormal quantities within the body; or if the normal process of elimination be in any way obstructed—a rapid accumulation will take place, so that there will be provided a fruitful soil for the growth of the bacilli and their toxins; more than this, there result ideal conditions for the development of mixed infections, in which the cocci join the bacilli, so that a curable disease often becomes transformed into a fatal one.

We have touched upon hereditary lesions of the heart and blood-vessels predisposing to tuberculosis. An impaired circulation means reduced oxidation, and consequently tissue starvation, particularly in the lungs; for under these conditions the vast capillary system opposes the already weakened cardiac contractions; and the pulmonary structures will not receive even their share of the deficient blood-supply. In this connection Sajous holds that such symptoms as pallor, muscular weakness, a thin, compressible pulse, an undeveloped or slightly dilated heart, anemia, anorexia, coldness of the extremities and habitual hypothermia, point to adrenal insufficiency. We may not agree with him as to the reason for these symptoms; but they do denote an ideal condition predisposing to tuberculous infection.

Chlorosis, an affection frequently related to tuberculosis, is referred variously to lesions of the vascular system, to adolescent disturbances, and to digestive disturbances; in each of these aspects is a relation logically established.

Alcohol certainly stands in a causative relation to tuberculosis. Pulmonary tuberculosis is almost invariably found in persons dying in the course of chronic alcoholism; tubercle of the peritoneum or pleura frequently accompanies cirrhosis; acute miliary tuberculosis finds alcoholics an easy prey. Kelynack finds 80 per cent. of pulmonary tuberculosis in patients dying of alcoholic neuritis; Osler finds a proportion of eight in eleven under the same circumstances. It is declared that pulmonary tuberculosis is more frequent in heavy drinkers than in people of moderate habits in the proportion of three to one. Lancereaux computes that more than one-half the cases of tuberculosis are due to alcoholism; and this, I believe, has been about the ratio in the medical wards of the City Hospital on Blackwell's Island.

It is difficult to explain the effects of alcohol. Like most of the simplest things in life, no definite agreement has ever been reached concerning its mode of working. Some consider that it is a preservative for living tissues as for others, because of the tendency to sclerosis which it furthers. Certain it is that there is no hardier stock than the wine-drinking countries. Others hold that chronic alcoholics are more liable to tuberculosis because of the resulting tissue impoverishment.

The bad effects attributed to alcohol lie largely in the state of affairs which it connotes; unsanitary habits, poverty, lack of nutrition, bad food, ill-ventilated living-rooms, and most of all a condition of the organism exhausted by overwork, in which the reserve force is all that is left to carry on the struggle for existence. Oftentimes alcohol is taken first with a view to keeping a defective economy up to the working point, perhaps in a tuberculous subject, or in one in whom all the conditions are receptive to tuberculosis; alcohol is then taken in increasing amounts to stimulate the flagging energies, thus making a bad matter worse. Some who contract tuberculosis have occupations conducive to alcoholism, such as workers in the liquor trade, barmen, waiters and hotel-servants, people who are thus employed because they are from their physical and moral make-up unsuited for another sort of work.

Poverty, with all that it implies—underfeeding, deficiency of sunlight, defective ventilation, overcrowding, uncleanliness, and bad drainage (which induces damp walls in houses), stands enormously in a causative relation to tuberculosis. Biggs has graphically demonstrated this by means of maps of various sections of this city. Bulstrode submits the death-rate from pulmonary tuberculosis in Hamburg among the several income tax classes (inclusive of the dependents of taxpayers). For incomes from nine to twelve hundred marks the death-rate is 55.4; for incomes of from twenty-five to fifty thousand marks the death-rate is 7.5; a proportion against the poorer classes of nearly eight to one.

I can but indicate a subtle relation which seems to obtain between insanity and tuberculosis. It seems that many in asylums who have tuberculosis contract, or at any rate develop the disease in these institutions. One account states that in 74 consecutive cases of pulmonary tuberculosis, in ages between twenty and sixty-two years, only three had evidence of tubercle before admission to the institution; it is furthermore observed that those who enter an asylum with tuberculosis have little chance of recovery while they are inmates.

The plan of sending tuberculosis patients away from the large cities into the country to enjoy the benefits of fresh air and water, sunshine and good food, is of course ideal therapeusis, yet if the consumptive were to go into farm-life and if he were to adopt habits which obtain in many rural districts, he would never get rid of his disease. Among these habits of life are, I believe: an execrable diet, to which meats other than bacon are practically strangers; canned fruits and vegetables and condensed milk being largely consumed, the fresh foodstuffs—including eggs—being sold for urban consumption; intermarriages through several generations in families living within a few miles square; morphinism; a seemingly innocuous imbibition of stomach bitters, cider, and perhaps other insidious fluids; and the

constipation habit, which if formed in the Winter months, through disinclination to venture to outhouses in the intense cold.

Altitude, temperature, moisture, season and soil may be predisposing factors; these need no amplification. Pulmonary tuberculosis occurs in inverse proportion to the height of a given district above the sea-level.

Tuberculosis is prone to follow upon other diseases, such as bronchitis, influenza and neglected colds; Fanning reports 28 cases in 100 in which pleurisy was antecedent; and 10 cases in 100 in which pneumonia was antecedent. In none of these cases was he able to get a definite history of auto-infection from other parts. Convalescents from the exanthemata, diphtheria and typhoid; and the co-existence of such affections as syphilis, malaria, and diabetes are powerful elements in the growth of tuberculosis. The Koch bacillus finds the sugar-containing tissues of the diabetic an unusually congenial host.

There are a number of trades which may stand in a causative relation to tuberculosis. In the excellent book entitled Dangerous Trades there are nearly sixty such occupations specifically considered.

Among predisposing causes we must include various forms of direct injury resulting in contusions, wounds and lacerations. These traumatisms greatly favor the development of the tubercular infection, but they are not essential; for the Koch bacillus may penetrate the unbroken skin and mucous membranes. It is very likely that traumatisms often result in tuberculosis by exciting nervous reactions.

And this suggests a consideration of the influence of psychism upon tuberculosis. It is difficult to gauge such influence; to compute the extent to which thought can affect the development of a leucocyte, the making of a drop of lymph, or the behavior of an excretory cell. The process is not susceptible of investigation by the microscope or by laboratory methods. Nevertheless it is essential, notably in tuberculosis, that the influence of the mind upon the body be not lost sight of. It is in every one's experience that mental perturbations derange the functions of various organs. Why may not acute shock, such as attends traumatism, or chronic shock, such as accompanies nerve exhaustion, or a protracted play of profound emotions, predispose to graver affections. Fanning indeed specifically states that overwork and anxiety have stood in a causative relation to tuberculosis in 34 per cent. of a series of his cases. And it is an altogether scientific, practical procedure to note that the vaso-motor system is an essential part of the machinery through which thought manifests itself; that passive congestion from any cause makes a tissue susceptible to tuberculous deposit; and that aberrations in the vaso-motor system constitute the likeliest factor to bring about blood-stasis.

Thus have I essayed to sketch briefly a few conditions predisposing to tuberculosis; it were impossible even to mention all such. For we are told that living itself is but the body's response to environmental influences, either physical or chemical in character; and these are about as numerous as are external phenomena. Personally, I would reserve the opinion that the whole of life is by no means comprehended in this statement; still it is valid as denoting the innumerable agencies which may make the organism receptive to tuberculous infection.

We may note, then, in a review of ante-natal conditions that fresh parental blood, and all that it connotes will surely beget healthy offspring, having tissues resistant to pathogenic agencies. Impure blood, and its associations in the parents will result in degenerated tissues in the offspring. This is true for other diseases in which a vicious nutrition is transmitted, as syphilis, alcoholism, epilepsy, asthma, insanity and cancer, as for tuberculosis; there is then no reason why the influnce of heredity in the latter should be ignored.

I am aware that the term scrofulosis, which I have used, is absent from the indices of up-to-date text-books; its manifestations being generally considered under the term tuberculosis. Yet I think that these are by no means synonymous terms. They are not the same disease, simply because they often co-exist. The term tuberculosis is meaningless, unless it implies the presence of the Koch bacillus; and this I believe, is by no means invariably the case in scrofula. This latter term may be unfortunate; but there is none other which represents, as it does, a distinct entity upon which the tubercle bacillus is often, but not always implanted. The scrofulous constitution is sensitive to all irritants and infections, not only to tuberculous infection. Struma is largely a transmitted condition; children are born manifesting it. We may well agree with Duckworth that "the influences by which scrofula has become a permanent element in human society have probably affected several generations in succession." In some cases there is, as we have noted, congenital infection; but in most cases there is no such infection. The parents may transmit an influence by toxins; but toxins cannot generate bacilli. Children are born with the scrofulous temperament, upon which many other factors soon react as complications. Such are unsanitary conditions, as impure air, lack of sunshine, poor food and drink, tenement life and the like. The tubercle bacillus becomes implanted; then skin lesions, abscesses, and enlarged joints follow: the scrofulous child is seldom born with these lesions.

With regard to the disease tuberculosis itself. The Koch bacillus is by no means the only factor to be dealt with. This bacillus has probably had an existence co-eval with man; it is all-pervading; the consumptive emits several billions of it during the twenty-four hours; yet most of us do not suffer from tuberculosis. The whole of tuberculosis is not comprised in this micro-organism, an index of a disease which is the resultant of many factors. Much has been done

for the relief of tuberculous patients; but the discovery of the Koch bacillus has not primarily influenced the treatment of the disease. It were irrational in the last degree to deny that drugs may be useful; nevertheless it is a striking fact that since Koch's discovery in 1881, there has not been one important addition to the pharmacopœia such as would prove directly efficacious against this bacillus. The anti-microbic drugs, which have been given internally with a view to destroying the bacilli, have generally been worse than useless. This is particularly true of those which have been malodorous and have nauseated. And if the ideas set forth in this paper are true, inhalants have been altogether unscientific drugs; and hyperalimentation, whenever it has deranged digestion and disturbed metabolism, has been vicious rather than beneficial in its effects.

Duckworth considers that the discovery of the Koch bacillus has not fundamentally changed the state of affairs. It has, however, and on the whole beneficially; but not always. For, as we have just noted, treatment by antiseptics taken internally and directed only to the elimination of micro-organisms has generally proved deleterious. But Koch's discovery has been beneficial in that it has led to the adoption of such principles of prophylaxis and sanitation as have been found effective against infections generally. The non-drug procedures, although they may have been directed against the bacillus, have nevertheless had their real usefulness in rendering the organism resistant to microbic infection. Our improvement in the treatment of tuberculosis lies, not in the use of any special bactericide, but in our appreciation and adoption of hygienic measures.

If the positions I have expressed as to the parts played by nutriment and digestion are sound, it is evident that the sooner the question of the identity of human and bovine tuberculosis is settled, the better it will be for rational medicine.

We have now several immunizing serums which promise much in the way of rendering the tissues resistant to tuberculous infection; it is heartily and most sincerely to be hoped that all expectations entertained for them will be realized. However these serums will never exceed in value such immunizing agents as fresh air, sunlight, cleanliness, baths, dry-walled, well-drained and well-constructed houses, good food and drink, and a general understanding and dissemination of the laws making for health.

To revert in conclusion to heredity, we may note that as functional rather than anatomical modifications are transmitted, much may be done in the way of education and physical training to eradicate vicious metabolism and tissue-tendencies; of course immediate results will not be expected.

I think, indeed, that the physician should take a very broad view of tuberculosis, a view the horizon of which would extend far beyond the incidents which are termed life and death. For this disease, which leaves its mark upon practically the whole of the race, is an index by inversion of human progress; the latter will advance in proportion as the former becomes eradicated. Descartes was not altogether right when he declared that if the race is ever to attain perfection it must be by means of the medical sciences. However, if the principles of hygiene and prophylaxis were universally grasped and applied, the race would surely be far advanced toward an ideal state.

THE INDICATIONS FOR THE LIGATION OF THE INTERNAL JUGULAR VEIN IN LATERAL SINUS THROMBOSIS.

BY SEYMOUR OPPENHEIMER, M.D.,
OF NEW YORK.

In considering the important question as to the advisability of shutting off the internal jugular vein from the general circulation with which it is in relation, in the presence of thrombosis of the lateral sinus, several aspects from which the problem must be viewed at once present themselves. The primary aspect of the subject resolving itself as to the advisability or non-advisability of ligating the vein at all; the opponents of this measure claiming that the procedure presents no features of value, as many cases in which it was apparently indicated have recovered without it. Another reason being that when ligated as a means of preventing infection and this is the practical object for which the operation is performed, it does not attain this end, as the infectious material may be carried into the lungs by the other internal jugular vein. And further, owing to the infiltration of the tissues in its immediate proximity, if often becomes extremely difficult to find the vein and remove the larger portion, while finally and this is the only objection that is at all worthy of consideration, the procedure adds greatly to the gravity of the operation.

While it is to a certain extent true that a small amount of infective material may become distributed through the opposite vein, yet this is of little practical moment if the affected sinus clot be thoroughly removed, the main bulk of the infection which is seriously impairing the health of the patient, being derived from the affected side and the consensus of otological opinion is apparently in favor of ligating the jugular under certain conditions which will be discussed later. While the operation is necessarily prolonged when in addition to the other requisite procedures, the vein and its important tributaries are ligated and exsected, yet compared with the prolonged and often fatal pyemia which may develop should this channel of infection not be removed, the dangers to the individual are not necessarily increased in my experience and the favorable results obtained, more than counterbalance the severity of the procedure at the time of operation. This is shown in the statistics prepared by Koerner, of thrombus of the lateral sinus in which in 42 cases, the jugular was ligated in 26 with 63.4 per cent. of cures, while in the remain-

ing 16 cases, in which the jugular was not ligated, there were only 42 per cent. cured. When the vein was tied before evacuation of the sinus in 19 cases, there were 68 per cent. of cures; when ligated after evacuation of the sinus, 60 per cent. recovered, while in the remaining one case of recovery, the vein was ligated without evacuation of the sinus. The same author has also reported 20 cases with 13 cures in his personal experience and advocates early ligation as a measure for the prevention of the passage of septic emboli into the circulation from the septic phlebitis of the lateral sinus.

Brieger ignores the general symptoms of pyemia in deciding the matter of ligation and considers it only justifiable when local indications exist, the systematic application of the procedure as an integral part of the operation for sinus phlebitis as he considers it, is never justified. Of course this is quite correct, for one is never justified in advocating ligation of the jugular in all cases of sinus thrombosis, but the local symptoms are often indistinguishable and cannot always be depended upon as an aid in determining the matter and to my mind the presence of pyemic symptoms before the sinus has been exposed, in conjunction with any local symptoms that may be present, should all be carefully weighed before determining the procedure to be acted upon, in a given case.

Jansen's experience is also in favor of ligation in the presence of definite symptoms, as in 7 cases where the vein was tied, 6 recovered, while in 8 cases in which the vein was ignored, but 5 recoveries ensued. Habermann holds somewhat of the contrary view and opposes a too arbitrary procedure respecting operation, not only in cases pertaining to ligation of the jugular but even in sinus phlebitis. He bases his belief of non-interference on a case of extradural abscess in the posterior cranial fossa, with a firm thrombus of the sinus and in which the walls of the jugular were quite discolored. He removed the discolored part of the vein but left the thrombus in the sinus undisturbed, yet the patient recovered. As far as the presence of a non-septic, firm thrombus limited to the sigmoid sinus is concerned, I would not of course interefere with the corresponding jugular, as in these cases ligation is never indicated, but when there are the least evidences of septic changes either in the walls of the vessel or in the contained thrombus, with these septic alterations extending to the jugular or passing through this vessel to the extent of producing pyemic symptoms, the jugular vein in my opinion should be ligated and the affected portion excised.

Brieger believes that the ligation is only justified when the thrombus has extended into the vein and cannot be positively prevented from passing toward the heart, although he is of the opinion that the closure of this pathway does not always insure against the escape into the circulation of particles from a disintegrating thrombus, as illustrated in a case under his care of sinus phlebitis, in which he made a low ligation of the jugular, yet pathological changes in the lungs followed the operation. Voss has also observed this late metastatic process after ligation in some cases, but he considers the chances for the patient as much better when the vein is ligatured, while Uchermann maintains that ligation need only be undertaken when the symptoms of pulmonary infarction are beginning to develop. I am not at all in sympathy with this opinion and in cases seen late where the first symptoms of septic changes are evident, although the sinus thrombus has existed for some time, I believe it will be wise to ligate the jugular immediately, the successful results obtained being dependent upon early and prompt closure and obliteration of this avenue of infection.

As pointed out by Whiting, the indications for this procedure vary as to whether the sinus has been exposed or not and if exposed, whether opened by the operator. The most difficult cases in which to determine whether ligation shall be performed or not, are those in which no operation has as yet been performed upon the sinus or mastoid, in other words, the primary ligation before exposing the sinus. This being illustrated by the following case:

J. M., male, thirty-four years of age; never had any trouble with his ears until six months previous to when he was first seen. At that time he developed an acute otitis media of the left side following swimming. The ear was treated with the usual home remedies and the abscess discharged on the third day. The discharge then gradually diminished in amount and two weeks later had entirely ceased, but he then commenced to complain of dull pain over the mastoid which was intermittent, but gradually increased in intensity. His appetite failed, he became anemic and lost considerable weight, frequently being incapacitated for work for several days at a time on account of the pain in his ear and general malaise. Three months later he stated that the mastoid became swollen and a small amount of thick, foul matter was constantly discharging from the ear. At this time he developed a cough and two weeks before being first seen he felt chilly at times and on the slightest exertion would perspire freely, diarrhea alternating with constipation also being present. On examination of the affected ear, there was seen a small perforation of Shrapnell's membrane, through which a drop of offensive greenish pus exuded. The posterior superior auditory canal wall was bulging and the mastoid and occipital region on the same side were edematous, as was also the upper cervical region. The man was markedly septic, his pulse was 130, while the temperature was 104° F., which three hours later, at the time of the operation, had dropped to 99° F.

Although he was already pyemic, it seemed a typical case in which to ligate the jugular as the first step of the procedure and after the usual aseptic precautions this was done low down in the neck, with in addition, ligation of the communicating veins. Two ligatures were used on

the jugular, the upper one being as high as possible and the entire vein was dissected out, considerable difficulty being experienced on account of the inflammatory infiltration of the surrounding tissues. The usual mastoid operation was then performed, free communication being made with the antrum and an enormous amount of fetid pus and necrosed bone were removed. The sinus was freely exposed, opened and contained the purulent disintegrating remains of a previous thrombus which had extended into the upper third of the jugular vein. The entire septic area was removed as far as possible, but considerable haste was necessary on account of the extremely precarious condition of the patient. The usual dressings were applied and after the intravenous injection of salt solution, the patient gradually rallied. The progress of the case was favorable until the fifth day, when the temperature rose to 102° F. and he complained of some pain and stiffness in the neck and a small purulent foci was evacuated immediately below the mastoid. The temperature then declined to normal, although there was a slight rise on the fourteenth day to 101.4° F., when a small abscess developed on the left forearm which was evacuated, after which the patient made a rapid recovery.

While in this case the indications seemed perfectly plain as regards primary ligation of the jugular, such is not always the case especially when the pyemic symptoms are not well marked, or when the vein itself gives no indication of septic or thrombotic changes. But not only in the milder cases but even under the most adverse conditions of purulent phlebitis of the sinus and vein, when metastatic abscesses are present in various portions of the body, a small proportion of these cases recover after extensive operative interference including resection of the jugular. But in those cases in which the infection has extended into the jugular vein and resulted in a suppurative phlebitis in order to anticipate or prevent the dissemination of the septic material, the vein should be ligatured as low down to the clavicle as possible and also a second ligature should be placed high up and the entire vein removed from the neck. Milligan reports such a case in which the internal jugular was ligated then the usual mastoid operation was performed and the sinus cleaned out through the opening of the vein in the neck. The patient promptly recovering. Zaufal also reports a similar case of septic otitic thrombosis of the sigmoid sinus, in which the vein was ligated and the sinus laid bare, recovery occurring in six weeks notwithstanding the development of metastatic abscesses in the glutei muscles and the development of purulent pleurisy. While Ridley records a case of pyemia terminating in recovery, in which he ligated the jugular, evacuated an epidural abscess and removed the purulent contents of the sinus.

The indications upon which one is justified in opening the jugular previous to operation upon the mastoid are principally, the presence of septicemia or pyemia as shown by the general condition of the patient and especially by the presence of a high temperature and rapid remissions even to subnormal, with quick alternations to the high point again in a few hours. In all cases where such a condition is suspected the temperature should be taken at least every hour. Repeated rigors are also observed and may be the first sign noticed. Great value from the diagnostic standpoint should be attributed to this symptom. Metastases of the septic material to the lungs, joints or any portion of the body, clearly indicate operative procedure and in the presence of such purulent collections, no hesitation or palliative measures should be advocated, but immediate ligation of the jugular should be performed, followed by the usual operation upon the purulent collection at its source. Occipital edema though rarely present, is of value when found and in addition to the clearly evident middle-ear suppuration and mastoiditis, would even in the absence of other symptoms indicate the involvement of the jugular and the consequent damming back of the blood in this region. The same may be said of edema of the eyelids of the corresponding side, except one would hardly be warranted in tying the vein unless other corroborative symptoms were also present.

Beginning or well marked neuroretinitis occupies to my mind, the same value as the former as an indication for operation, while tenderness along the jugular in the neck, with the presence of a cord-like sensation under the fingers of the surgeon, is undoubtedly the most reliable local symptom and when such is present in a given case, I would not hesitate to ligate and remove the diseased vein before the mastoid was explored. Chipault advises in these cases, that the more radical the operation the better will be the results and to obtain a complete removal of the purulent foci he ligates the jugular and removes it, then ligates the transverse sinus as near as possible to the torcular and performs the usual mastoid operation, with complete opening of the sigmoid sinus and lavages the parts twice daily. While this procedure is based upon the very sound premises that isolation should always be obtained before evacuation, in order to avoid dissipation of septic emboli, I question whether it is judicious or necessary, in the large majority of cases, to apply a ligature above the knee of the sinus as the establishment of free hemorrhage from this end washes out the thrombus and accomplishes the purpose.

Viereck clearly indicates this phase of the subject when he states that ligation of the jugular in operating for thrombosis of the sinus, is not generally adopted on account of some slight danger connected with it and of the possibility of impeding the outflow of the facial and cranial veins. Therefore its beneficial effects should be demonstrated by large and accurate statistics from which however should be excluded deaths from other causes such as meningitis, cerebral abscess, delayed operation and previous metastases. The use of the ligature is indicated in all cases where

there is danger of pyemic or localized metastases, and its application prevents pyemic infection, with greater safety and assurance, than does simple opening of the sinus. Therefore it ought always to precede the latter, thus preventing any danger of the breaking up of the thrombus and the aspiration of an air embolus.

Of the lesser pyemic symptoms which should be taken into consideration in determining operative procedures, profuse sweating without apparent cause requires mention, while vomiting, anorexia and accelerated pulse rate in conjunction with an otherwise obscure history, may be of service in elucidating an accurate understanding of the individual case. In but one of the three cases herewith recorded was pressure over the internal jugular at the upper third portion of its course, productive of pain.

Jansen operates as soon as it becomes evident that there is septic degeneration of the clot and ligates the jugular without further investigation of the sinus. He reports 6 cases, 4 of whom succumbed. While Eulenstein reports a successful case; Köhler an unsuccessful one and Green states that before opening the sinus, the jugular had better be ligated to prevent displacement of the thrombus and resulting general infection, but the danger of a prolonged operation, or infiltration of the neck from a gravitation abscess through the base of the mastoid, or from periphlebitis, may render ligation inadvisable or impossible. Pritchard also holds to the same opinion, inasmuch as he believes the jugular should first be ligated and when the septic process is far advanced, it may be advisable to dissect out the vein even to the extent of its whole course in the neck. Such apparently heroic measures sometimes saving an otherwise hopeless case. While Church inclines to a somewhat opposite view and believes that it is not necessary or advisable unless the clot is septic or broken down, while if the sinus is filled with a fibrinous clot, ligation is clearly not indicated.

Of the second class or those cases in which the sinus has been exposed but not opened, the indications for ligating the jugular before further operative procedure in the direction of the sinus, are but two in number, the first practically being the one of greatest importance. When in this class, the presence of a clot has been determined by the usual methods and aspiration shows that the lower portion is beginning to disintegrate, one is certainly justified in immediately ligating the vein and I believe this in indicated even more forcibly when septic symptoms of even a minor degree are present, although no emboli have as yet entered the circulation. This was the indication upon which ligation was performed in the following case:

T. G., male, aged thirty years. When ten years of age he had an attack of measles and since then he has had an intermittent purulent discharge from the right ear. At times it would almost disappear and then would discharge profusely following repeated attacks of coryza. While the ear was slightly painful at times, yet it was never severe enough to cause complaint until five months ago, when the discharge gradually diminished in amount and the pain increased in intensity, causing considerable suffering especially early in the morning. Examination showed a slight purulent discharge from the right canal, with an intensely foul odor. There was a small patch of caries on the posterior wall and the mastoid was considerably swollen and tender upon the lightest touch. The occipital tissues and the parts over the upper portion of the internal jugular vein were also in the same condition. There were the physical appearances of sepsis, with cachectic features, coated tongue and a constant diarrhea; pulse 120, temperature 103° F.

Immediate operation was advised and performed the same day under ether anesthesia. The auditory canal was cleansed and a probe passed through the sinus in the wall, well into the mastoid. The usual mastoid operation was then performed, but on account of the extensive destruction of the osseous cortex and cells, the pus and débris were readily removed with a spoon curette. The inner table over the sinus was in part destroyed and from the apparently septic condition of the contained thrombus, it was necessary to ligate the jugular vein, which was done immediately above the clavicle and a second ligature was placed as high up as possible. The vein was then dissected out in its entirety and the smaller communicating veins were ligated as this portion of the operation was proceeded with. The jugular was found to be filled in its superior part with pus and the remains of a broken down thrombus. At this stage of the operation the patient began to do very badly and an intravenous injection of salt solution was given with a most beneficial result, oxygen also being administered during the remainder of the operation.

The sinus was then opened and found to be in the same condition as the vein and the contents were removed, although great difficulty was experienced in releasing the upper end of the thrombus which was still firm. The bone was chiseled away almost to the torcular before free hemorrhage could be established. I believe in this case that the thrombus extended beyond into the lateral sinus of the opposite side. On account of the extremely bad condition of the patient, the parts were rapidly cleansed and packed with gauze and the usual dressings applied. The temperature, low for four days, rose to 103° F., and it was found that there existed considerable pus under the sternomastoid muscle. This was removed and he slowly improved, although the blue hue of the face sometimes observed after removing the jugular vein, remained for nearly two weeks. The temperature then returned to normal until the eighteenth day, when it suddenly rose to 101.2° F. without apparent cause, the incisions both in the neck and mastoid appearing perfectly healthy. It, however, only remained at this level for several hours, then declined and the case progressed through the usual course without

further trouble. When seen, four months later, he had nearly regained his former weight and presented all the appearances of good health.

Possibly this case should have had the jugular ligated as a preliminary procedure to the mastoid operation, as in the former case; the indications being fairly well marked, but on account of a difference of opinion among the medical gentlemen in attendance as to the relative value of the symptoms, the inability to obtain the consent of the patient to an operation involving an incision in the neck until it be found to be absolutely necessary, and the conjoint presence of tertian fever, the malaria plasmodia being found in profusion in the blood, this was not done until the condition of the sinus was ascertained by inspection.

The second indication for ligating the jugular after exposing the sinus, is the presence to the eye of the surgeon of the movements of respiration transmitted to the sinus, the dangers of embolism of air under these conditions and the implied presence of a thrombus entering well into the torcular, warranting the immediate ligation of the vein in the neck before the sinus is opened. This must be extremely rare, and it has been my fortune not to have seen a case in which this phenomena was well marked.

Joachim reported several similar cases, one in which the sinus was exposed and then the vein ligated, but as the case was profoundly septic, death resulted from metastatic pneumonia. The other he reported was operated on in the same way, but a solid clot was present. He believes that statistics show a greater preponderance of recoveries when the jugular has been ligated and considers it the part of prudence to tie the vein, although cases have recovered without ligation of the jugular, even when the lungs had already shown metastatic deposits. In the discussion following the reading of his paper, it was elicited that ligation was the course to pursue in all these cases where septic symptoms were present, as it did not add much to the gravity of the case and it prevented the septic infection from becoming more general. As pointed out by Buck if, upon exposing the sinus, the wall is seen to be ulcerated and purulent fluid and broken down débris are contained in the vessel, it is advisable to stop operative procedures in that direction and ligate the jugular before removing the diseased tissue. If the jugular is tied high up and does not contain a thrombus, no further interference will be necessary, but if the thrombus has extended downwards or if phlebitis be present, a second ligature should be placed as before mentioned and the vein removed.

From the local symptoms, it is not always possible to ascertain that the jugular is infected, as there may be swelling of the neck and even tenderness along the jugular, which may, as pointed out by Brieger, be due to pathological changes in the lymph glands, such a case coming under my observation very recently, in which chronic suppuration of the middle ear was followed by mastoid disease and these symptoms referred to the cervical region were quite prominent. Considerable doubt was entertained however as to their being directly connected with the aural trouble and on performing the usual mastoid operation with exposure of the sinus, the latter was found to be perfectly normal. Forty-eight hours later the condition in the neck was cleared up by the development of erysipelas, which fortunately was a mild attack and no trouble was experienced other than that seen in the usual mastoid case. I think, however, that enlargement of the cervical lymph glands and infiltration of the soft tissues is a very valuable sign indicative of phlebitis and thrombosis of the internal jugular, the condylar and the deeper veins of the neck. This infiltration often undergoes purulent inflammation. In two cases which I have seen, the abscess formation seemed to localize for the time being the process of disintegration and formed a barrier between the lungs and the abscess, by the formation of a thrombus in the lower portion of the vein.

The third group of cases, are those in which the sinus has been opened and a large thrombus extending down into the jugular with coexisting purulent disintegration is seen, but which has not before been recognized. Under these conditions it is practically impossible to remove the putrid mass without dislodging dangerous particles and the indications are perfectly clear to ligate the jugular vein in order to prevent the general dissemination of the septic material.

Another indication for ligation which holds good under the same circumstances, is the presence of a large firm thrombus, filling the sinus and extending well down into the vein. After the sinus has been opened and the presence of such a clot determined, it is manifestly poor surgery to allow it to remain even should no septic or disintegrating changes be present in the given case, and as it is practically impossible to remove it through the opening in the sinus, without the danger of seriously damaging the deep tissues of the neck, it is necessary to ligate the jugular in order to effect thorough removal with the least danger to the patient. As the presence of such a clot prevents the flow of blood and it is necessary to reestablish the circulation, one is perfectly justified even if the presence of the thrombus in the upper portion of the jugular is not recognized, in ligating the vein, whenever it is impossible to produce a free flow of blood after the sinus has been evacuated as thoroughly as possible.

Schwartze, Poli, Grunert, Alderton, Kerr and others have reported cases of interest in this connection, while Eulenstein records an exceedingly instructive case of otitic pyemia, in which ligation of the jugular was performed three days after surgical exposure of the middle-ear cavity, lateral sinus, posterior cerebral fossa and evacuation of a large pus cavity near the jugular bulb. As pyemic symptoms continued after the operation, ligation was considered as a last resort, although there were no symptoms of a thrombosed

condition of the vein; the patient recovering Similar to this was the case reported by Toeplitz, of pyemia, with the development of abscesses in various parts of the body and the complete recovery of the patient after cleaning out the lateral sinus and ligating the vein. While as an example of the extremely serious condition the patient may be in and yet recover, is the case of Ballance's, of a pregnant woman, twenty-four years old, with a severe suppurative otitis, swelling of the posterior canal wall, the presence of granulation tissue and a discharging sinus, double optic neuritis and chills with fluctuating temperature. The mastoid was opened, the jugular was ligated in two places and incised and was found not to contain a thrombus, but was collapsed owing to the obstruction of the blood current higher up. Metastatic abscesses formed in the shoulder, tonsil and leg, there was sinus thrombosis with subdural abscess. Premature delivery occurred and in addition to suppurating tonsillitis, there were two attacks of erysipelas and jaundice.

Cheatle in expressing his views as to the indications for jugular ligation, believes that it is not always necessary in thrombosis of the lateral sinus, with which I am in perfect accord, but to use his words, "If it seems that there is healthy looking clot well below the broken-down area, ligation of the vein is not necessary, but it must be remembered that the presence of even one rigor demands immediate operation." As an example of the third group, or those in which the jugular is ligated after the sinus has been exposed and opened, the following case is presented.

C. Y., male, aged eighteen years. Chronic suppurative otitis media since his fourth year following scarlet fever. Profuse discharge for a number of years with a fetid odor. Has had local non-surgical treatment off and on, but with no lasting results. One week before I saw him he went swimming and within a few hours, the discharge from the right ear practically ceased. The following day he complained of pain over the mastoid, with gradually increasing malaise, anorexia and on the day previous to when first seen, he suffered from chilly sensations. On examination, the mastoid was swollen, boggy and there was slight tenderness on deep pressure along the upper part of the jugular vein. A small amount of foul pus was removed from the middle ear and the posterior superior wall was found to be bulging into the canal. The temperature was 102° F. in the morning and varied from 99.2° to 104° F. during the day.

The following day the mastoid was opened under ether anesthesia and was found filled with foul pus and granulation tissue. Communication with the middle ear was established and a large quantity of necrosed bone was removed. The sigmoid sinus was then exposed and laid freely open, when a clot was found almost completely filling its walls and extending into the jugular vein. Beginning disintegration of the thrombus was evident, so the internal jugular was ligated low down in the neck. The sinus was then evacuated and the entire field of operation was cleansed with bichloride solution, followed by packing with iodoform gauze. The following day the temperature was 101° F. and after the second day returned to normal. The patient made a rapid recovery and after a year's interval, he remains perfectly well with no discharge from the ear.

A number of similar cases have been recorded by McKernon and he considers as indications for ligating the vein after the sinus has been opened, the presence of a disintegrating clot or pus. While he also states that in the presence of marked physical signs of jugular involvement, it is good advice to ligate the vein before opening the sinus above, provided we are sure as to what we are going to find, but in the majority of cases, no positive diagnosis as to the condition of the jugular can be made before the sinus operation.

From the cases of sinus phlebitis both with and without involvement of the jugular vein, that have come under my observation, it has seemed advisable for the best interests of the patient to ligate the vein whenever local symptoms indicating its involvement were present. When the patient presented evidences of sepsis and especially irregular temperature and rigors and when after the mastoid has been opened, the presence of pus was evident in the vessel.

Changes in the Cornell University Medical College.—Dr. Alexander, Professor of Genito-urinary Diseases, has obtained a leave of absence on account of illness, and this year the lectures upon the surgery of the genito-urinary tract will be given by Dr. Charles L. Gibson.

CHORDA VENEREA.*

BY G. S. PETERKIN, M.D.,
OF SEATTLE, WASHINGTON.

Clinical Definition.—A complication of acute gonorrhea, characterized by intense pain during erections and the bending of the penis in an abnormal direction. This condition is considered a complication of gonorrhea on the premises that an acute, simple or an uncomplicated case of gonorrhea is a specific infectious inflammation of the mucous membrane of the anterior urethra and is limited to the epithelial layers of this membrane, for the reason that this tissue, the epithelium, is the normal feeding ground of the exciting cause of the disease, the gonococcus of Neisser. Therefore any extension of the inflammation beyond the epithelium into the adjacent tissue, is a complication.

Pathology.—The gonococci, usually within twenty-four to forty-eight hours, penetrate the epithelial layers of the mucous membrane and cause the following phenomena to take place in the submucosa: Congestion of blood-vessels; hypersecretion of glandular tissue; diapedesis (exudation of the elements of the blood); phagocytosis; production of embryonic cells.

Congestion of blood-vessels, diapedesis, phagocytosis and production of embryonic cells, interpreted in a general manner, signify infiltration of the tissues of the penis by the contents of the blood-vessels, the red and white blood-corpuscles, serum etc. And in addition to this, there is the formation of fibrinous coagula and embryonic cells. Histologically, the tissues involved are mainly of the dilatable character known as spongy tissue. The shape and average size of the penis can readily be called to mind. Practically, from a mechanical point of view, this organ consists of three cylindrical tubes of spongy, flexible tissue. Macroscopically, they are separate and distinct from one another and placed with their long diameters parallel and in such apposition, that two of the tubes, the "corpora cavernosa" form the base of a triangle and the dorsum of the penis, and the remaining tube, the "corpus spongiosum" through which the urethra passes, the apex of the triangle and the inferior surface of the penis. Microscopically, the tissues comprising the urethra and the three corpora, are intimately enough related to permit an inflammation to extend by continuity to all the tissues comprising them. Especially is this true of the relationship between the urethra and the corpus spongiosum.

Infiltration of a portion of the urethra will cause it to become thickened, friable, lose its elasticity, and, on turgescence of the organ, crack in the area of infiltration, producing a fissure and the symptom of severe pain, that is characteristic of fissures even in less sensitive parts of the body. Infiltration of a portion of the corpus spongiosum will interfere with the dilatability of the consolidated area. On turgescence of the organ, this area will not dilate, and through interference with the circulation, the dilation of the distal portion of the corpus spongiosum beyond it will also be incomplete. The two corpora cavernosa becoming completely dilated and also the proximal uninfiltrated portion of the corpus spongiosum, there will naturally result the physical symptom of chordee, a deflection toward the point of least resistance, which in this case is the partially dilated, uninfiltrated distal portion of the corpus spongiosum, with the consolidated area as the fulcrum. The direction of the deflection is usually downward, as the inferior surface of the corpus spongiosum is the portion of the penis most frequently affected.

The character of the chordee depends upon the amount of tissue infiltrated in depth rather than extent. It may vary in any degree, from the mildest form, which is caused by infiltration of all the tissues of the urethra proper, the epithelium, the submucosa, mucosa and the layer of unstriped muscular fibers, to the severest, which includes the mildest with extension of the inflammatory infiltration of the trabeculæ of the corpus spongiosum, rendering them non-extensible, and the filling of the intrabecular spaces with inflammatory exudation that prevents their dilation during erection.

Etiology.—Anything that will aid the gonococci to penetrate beneath the epithelial layers, as intensity of infection; lack of resistance of the tissues to infection; "traumatisms that do damage to the epithelial layers of the mucous membrane, such as injections destroying the epithelium, misuse of a sharp pointed syringe, clumsiness in use of sharp irrigation nozzles, antrophores, sounds or catheters and especially violence in irrigations."*

Symptomatology.—Intense pain during erections and bending of penis in abnormal direction. The intensity of the pain is so severe, it is almost indescribable; by some the pain has been described as "the sensation of a hot wire drawn through the penis like the cord of a bow" (Valentine). Patients will often tell you that they feel as if they could bite a nail in two. It has frequently led to attempts to break the chordee; that is to straighten the organ by mechanical force, as by placing the penis against a resisting surface and striking it with some object, as the fist, the back of a book, etc. One case often quoted, is that of a patient who placed his penis upon the window ledge and then violently pulled down the sash upon it. Others have attempted relief by intercourse. The effect of such violence is to severely aggravate the already existing inflammatory condition, because of the lessened resistance of the injured tissue to further infection, and the formation of numerous foci of laceration, that may lead to deeper infection and terminate in chronic cavernitis; rupture of the urethra with a fatal hemorrhage, infiltration of tissue with urine, that may be followed by a urinary fistula, septicemia, gangrene of penis, etc. From any of these

* Presented before the Second Annual Meeting of the American Urological Association, at New Orleans.

* The Irrigation Treatment of Gonorrhea (Valentine). Given by him as the causes of cavernitis.

complications, if death does not occur, there will result a deformity of the penis, which will cause impotency from inability to have properly formed erections.

Prognosis.—Statistics not obtainable. Complete recovery is the rule. However, chordee no doubt increases the percentage of chronic gonorrhea, because of the greater possibilities of deep infection caused by this complication. It may terminate in chronic cavernitis and deformity of penis that will be so great during erection as to prevent intercourse, and thus cause impotency. Death from causes previously related under "Symptomatology" may possibly result, when violence is used to straighten the organ during an attack.

Preventive Treatment.—This demands the eradication of the causes of gonorrhea. Realization of the vastness of this branch of preventive medicine, "The Prevention of Venereal Diseases" prohibits any statements on the preventives of gonorrhea, for they would be not only foreign to the object of this paper, but unjust to a subject, whose vital importance to humanity, requires due deliberation and the best thoughts that the scientific and humanitarian mind of man can give.

The working premises upon which the theory of actual treatment is based, are as follows: Chordee, a complication of acute gonorrhea, due to the extension of the inflammation to the deeper tissues of the penis. Acute Uncomplicated Gonorrhea: A specific inflammation of the mucous membrane of the anterior urethra, practically conceived of as a local ulcerating surface, that physical rest cannot be given to, because located in a member of the body, the penis, which, from its nature and function, cannot be placed in a state of absolute quietness; neither can the ulcer be kept free from irritation, because located upon the surface of a canal, the urethra, through which passes an acid excretion of the body; nor can the ulcer be kept surgically clean, because situated in the urethral canal, the configuration and form of which retain the discharge, prevents free drainage, an ocular view of the inflamed surface and direct local treatment. Moreover, the ulceration is so inaccessibly situated and on a delicate mucous membrane, that local application of medicine to the inflamed area is impossible, unless the medicine at the same time comes in contact with the surrounding tissues. Therefore, the severe measures necessary to the destruction of the specific infection, the gonococci, cannot be used without causing greater damage to the surrounding tissues than would compensate for the benefit derived from the death of the bacteria.

In summing up our working premises, the following conclusions are deduced: That gonorrhea, therefore chordee, is a local diseased area inaccessibly situated, the sucessful treatment of which will depend upon one's ability to successfully devise the means of correctly applying to it the recognized principle of antiseptic and aseptic surgery.

The method of treatment to be followed will be limited to any procedure that will improve the constitutional condition of the patient, overcoming the natural obstacles to surgical treatment previously mentioned and, in so doing, aid nature in obtaining rest, surgical cleanliness, reduction of congestion and absorption of inflammatory exudation. The principal means of obtaining the above results, rest, surgical cleanliness, reduction of congestion, and absorption of inflammatory products, I will endeavor to give, and shall attempt to classify under these headings in proportion as they attain their objects, though the difficulty of so doing satisfactorily, can be appreciated, as many of these means serve in varying degrees more than one purpose:

1. Rest, obtained (*a*) through general physical rest, confinement to bed (seldom possible); (*b*) through prevention of erections. This necessitates prevention of congestion and irritation of the sexual organs, their nerves and centers, and will be considered in combination with the second and third classifications.

2. Surgical cleanliness and freedom from irritation obtained, (*a*) through mechanical drainage, meatotomy to extent of three-fourths of the diameter of the urethra, (*b*) through flushing of urethra by drinking large quantities of water, a glass every two hours (no alcohol, no carbonated waters); (*c*) through keeping drainage free, by not applying the cotton or other dressing too closely to the meatus, and by frequently changing it; (*d*) through preventing reinfection from absorption of infectious matter of the discharge that accumulates upon the cotton applied to meatus, by using an antiseptic upon the cotton; (*e*) through always allowing the penis to hang down in order to give the discharge the benefit of gravity; (*f*) through having the suspensory fit properly, that is, support the testicles well, and not constrict the penis near its base, thus interfering with the circulation and by retaining the discharge on the proximal side of the obstruction, endangering the posturethra and, by interfering with circulation of distal side, favoring congestion of the urethra anterior to the obstruction; (*g*) through instructing the patient not to strip the urethra, and thus disseminate the infection and injure the inflamed membrane.

3. *Reduction of Congestion Obtained.*—(*a*) Through regulating the diet, in ordinary cases to extent of eschewing highly seasoned foods and pastry, and causing meals to be taken regularly and eaten slowly. Otherwise, the natural daily diet; including tea or coffee once a day, which does not appear to affect the inflammatory condition adversely, but rather aids it by diminishing the mental depression that frequently accompanies this disease. In severe cases a fluid diet is indicated. (*b*) Through instructing the patient to sleep on a hard mattress with light covering. Not to rest on back, because the abdominal organs gravitating toward the pelvis, by their pressure, will cause congestion of pelvic organs and erection. Prevented by tying a towel about the abdomen and placing the knot in the small of

the back. (*c*) Through instructing the patient to absolutely avoid sexual intercourse, even the loving attentions sometimes deemed essential to wooing; and all scenes, literature and conversation that will evoke licentious thoughts; and by having him empty his bladder at least once during the night. An alarm clock set at about one hour before the usual time of rising, will aid in overcoming forgetfulness. (*d*) Through the administration of oleum santali (pure) c.c. .60 every two hours, until four doses are taken, then c.c. .30 every four hours if posturethra is involved or the dilution of the urine by ingestion of water does not relieve the irritation caused by the acid urine and urinary solids. (*e*) Through keeping the bowels free with magnesium sulphate gm. 3.75 night and morning, thus depleting the pelvic circulation. (*f*) Through instructing patient to avoid getting feet wet and sudden changes of temperature. (*g*) Through instructing the patient to bathe the penis at least twice daily, if not oftener, in water as hot as can be borne. This not only diminishes congestion, promotes phagocytosis and absorption of inflammatory exudation, but frees the glued together meatus and facilitates the escape of the discharge and diminishes the suffering of the patient. If possible, a sitzbath should be taken at night. And if the posterior urethra is involved or erections frequent, in addition an enema of one pint of hot water with one teaspoonful of salt in it, is of benefit, and can be repeated in the morning if necessary. (*h*) Through aseptic irrigations of the urethra twice daily with at least one liter of a hot solution. Intravesical irrigations are indicated, especially if posterior urethra is involved. However, the therapeutic advantages to be derived from irrigations will depend upon the gentleness and skill of the administrator.

Results are advantageous by mechanically rendering the whole canal of the urethra and the inflamed surface, without injury to it, free from the discharge that may produce additional foci for deeper infection, from stimulating the circulation by the heat and friction. This relieves the congestion, aiding phagocytosis and promotes the absorption of the inflammatory exudate. (If the theory is true that large volumes of hot water (110° to 120° F.) when used in the urethra produces a species of artificial edema.) These urethral lavages, by causing a swelling of the epithelial cells, aid in the cure of gonorrhea by retarding the progress of penetration of the gonococci by mechanically obstructing their advance, through obliterating the spaces between the epithelial cells. For, as demonstrated by Finger, Durkler, Rosinsky, Jadassohn and others, the gonococci penetrate the epithelial layers by gliding between the cells.

The ideal solution to be used, is one that will have the power of penetrating the tissues, yet possesses such bactericidal strength that it will kill the gonococci, but not injure the mucous membrane. The newer silver salts, such as argonin, argentamin, protargol, largin, argyrol, etc., at present best fulfil this object. The one to use depends upon the severity and character of the inflammation.

To recapitulate the bactericidal benefit derived from irrigation with a hot solution 110° to 120° F. can be explained on the following theoretical grounds: That irrigation causing swelling of epithelial cells prevents penetration of the bacteria to the deeper tissues. The bacteria thus retarded are more apt to be affected by the antiseptics used. That the mechanical removal of the discharge aids phagocytosis, prevents dissemination of infection; that the heat diminishes congestion, stimulating the circulation and aids phagocytosis. Phagocytosis is nature's method of destroying the gonococci. Irrigation therefore, derives its bactericidal value from placing the gonococci between two fires: The antiseptics of man and the phagocytosis of nature.

The foregoing statements, as previously intimated, are an attempt to classify the general surgical principles and theories useful in the treatment of gonorrhea and prevention of chordee.

The main object, however, in writing this paper, has been to add to these general principles a hygienic detail in treatment, the value of which I believe as yet is only partly recognized and that is massage of the prostate and seminal vesicles in acute gonorrhea. For massage of the prostate and seminal vesicles in acute gonorrhea, the following advantages in treatment may be claimed: In massage we have an efficient method of preventing erections; as a result, the pain of chordee is obviated and congestion, a predisposing factor to the further extension and continuance of the gonorrheal infection, lessened; in massage we have the means of producing a beneficial psychological effect upon the patient. The theory of the treatment is explained to the patient and he is told how the semen is stored in the seminal vesicles until becoming overdistended, they excite the sexual centers and cause erections and ejaculation. And he is then informed that by massage, the overdistention is relieved and the semen expelled, and therefore he cannot have erections. The psychological effect thus produced is often very effective in preventing sexual excitement and is of special service in the case of those whose social life or occupation brings them in contact with women, as for instance, married men. Moreover, as a passing comment before proceeding, in the neurotic, in whom emissions without intercourse are associated with the horrors of the damned, silence on the theories of emissions, an optimistic view of the case and a systematic robbery of the seminal vesicles have their advantages. In massage we have a hygienic method of procedure that no longer necessitates the disordering of the systemic condition with bromides, the monobromates of camphor, codeine, etc. Moreover, in all possibilities we have in it the means of diminishing the percentage of cases of infection of the prostate and the posterior urethra. And in practising massage, we have the immense advantage of early diagnosing the involvement

of the prostate; and, in the frequent examinations of the normal prostate, have the opportunity of training the tactical sensibilities to a degree that their value as essential aids to the diagnosing of prostatic diseases is realized in actual practice as well as in theory.

The premises for the above conclusions are as follows: The sufferer from gonorrhea is accustomed to sexual intercourse, *i.e.*, the active physiological phenomena of the sexual instinct, the secretion of the semen, erections and ejaculation, have become a physiological law that an acute gonorrhea does not interfere with. On the contrary there is an increase in the frequency of erections, in the amount of semen produced, and, if it were not for the cessation of sexual intercourse (a physiological habit), there would be an increase in the frequency of emissions. In other words, as a concomitant of gonorrhea, there is the following abnormal stimulus to the nerves of the sexual organs and centers: (1) The congestion of inflammation; (2) presence and multiplication of gonoccocci; (3) production of toxines; (4) an increase in cell-proliferation; (5) an exposure of the nerve-endings to irritation through destruction of tissue.

In these abnormal stimuli can be found an explanation for the increased activity in the secretory function of the sexual organs that causes an overproduction of semen, and in the presence of the inflammation that prevents emissions in the normal manner, by intercourse and sometimes nocturnal pollutions because of pain, an aid to overdistention of the seminal vesicles and prostate. This overdistention in turn, by increasing the pressure on the already hyperesthetic nerves of the sexual organs, adds to the frequency of erections and the severity of the congestion, both conditions act as hindrances to the successful treatment of the disease.

The protection that the massage at this acute period of gonorrheal infection offers to the posturethra and prostate, is explained on the following grounds: (1) Congestion predisposes to inflammation; congestion is relieved. (2) According to Lydston, of Chicago, the ejaculation of the semen is accompanied by a syringe-like action on the part of the bulbo-cavernosa muscle that will aspirate the semen mixed with the anterior urethral secretion into the posturethra and thus cause infection of the prostate.

The reader of Fuller's* logical and convincing applications of the principles of the mechanics of the heart to the sexual apparatus, will perceive in Lydston's statement, an extension of this principle to the bulbo-cavernosa muscles and therefore a theory of practical utility. If the anatomical facts are recalled, that owing to the curvature of the proximal end of the anterior urethra downward and backward, the glands of Leiter and the crypts of Morgagni, here have their openings directed backward, and on account of the same physical fact, their contents and any inflammatory secretion in this portion of the urethra will gravitate toward the compressor muscle, one will perceive an additional factor (the accumulation of infectious material against the compressor muscle), increasing the percentage of cases of posterior urethritis and prostatitis, this syringe-like action of the bulbo-cavernosa muscles occurring.

Method of Conducting Massage of the Prostate in Acute Gonorrhea.—Patient first voids his urine in ignition tubes. The anterior urethra is then thoroughly irrigated by Janet's method with some hot mild antiseptic solution, such as potassium permanganate 1-6,000, protargol 1-1,000, etc., so as to render it free from the discharge, especially the proximal end previously referred to. Next the bladder is well filled with a solution of the same strength, a small quantity of which, sufficient to relieve the feeling of overdistention is at once voided into a glass urinal and saved for comparison with the remainder, which is retained in the bladder until after the massage is completed, The solution in the bladder mainly serves the mechanical purpose of cleansing the posterior urethra before and after massage and as an aid to massage, by distending the bladder so that when pressure is brought to bear upon it, with one hand, the prostate is brought near the massaging finger. The patient is placed upon the table upon his back, a towel placed under his buttocks, legs flexed and rotated outward, the heel of one foot being placed upon the instep of the other. The index finger of the right hand of the operator (a thin rubber glove is worn) is then well covered with vaseline. During inspiration, the index finger is inserted into the rectum. Then with the left hand pushing down the distended bladder, the prostate and seminal vesicles are thoroughly examined and then gently, not violently, stripped until they are emptied of their contents. In so doing the overdistended and congested seminal vesicles are relieved in a passive manner that will avoid the suction action of the bulbo-cavernosa muscle. Massage being completed, the patient immediately empties his bladder of its contents. And if any infectious matter does enter the posterior urethra from the anterior, or is squeezed from the prostatic ducts affected with an incipient form of prostatitis, it is at once washed out. As an additional protection against infection, the bladder, before dismissing the patient, is again washed with a normal salt solution, or preferably, a 4-percent. boracic acid solution. This injection once more cleanses the urethra and bladder, has some antiseptic value, and is of special service as it prevents the distressing tenesmus that occasionally follows intravesicular irrigations, and is to be avoided.

The frequency with which massage should be practised depends upon the patient's sexual habits and the rapidity with which the vesicles and prostate become distended. Usually once or twice a week is sufficient.

In conclusion, I will state that this paper is the result of a clinical observation of 54 cases of gonorrhea, 20 of which were acute primary gonorrheas and of 10 circumcisions (uncompli-

*Disorders of the Male Sexual Organs (Fuller), page 51.

cated by gonorrhea), 5 of which were massaged to prevent erections. Of the 5 massaged, none were troubled with erections. Of the 5 unmassaged, 3 were. With this number of cases, I consider my experience to date sufficient only to warrant the advocacy of this treatment of chorda verenea in the hope that time and the experience of others will demonstrate its practical utility.

ON THE REFLEX ERUPTIONS OF THE SKIN FROM MORBID ALTERATIONS IN THE MALE URETHRA.*

BY A. RAVOGLI, M.D.,
OF CINCINNATI, OHIO.

The diseased condition of the urethra is often the cause of reflex skin eruptions. In acute urethritis, we often meet with edema of the prepuce with lymphangitis, but these are not of the kind which we have under consideration. The balsamic erythema, which is found as a result of the ingestion of the oil of copaiba or of the santol, is only a remedial eruption and has nothing to do with the urethritis.

The affections of the skin which originate from chronic disturbances of the urethra, are of a reflex nature and can be reduced to herpes and pruritus.

Herpes.—Often a man complains of relapsing herpes progenialis, and he is unable to conceive the reason of the recurrence of the affection. The eruption, vesicular in character, appears suddenly in the form of small vesicles, five, six or more aggregated together, sometimes separated. They usually make their appearance in the sulco balano preputiale, around the frenulum and on the internal surface of the prepuce. Sometimes they will be found on the dorsum penis, and in some aggravated cases the vesicles may appear also on the scrotum. The appearance of the vesicles is preceded and also accompanied with a slight itching sensation. The vesicles are filled with clear serum, and their cover being very thin, easily breaks, and leaves round superficial excoriations, which have a yellowish surface, oozing a thin whitish serum. After five or six days, new epidermic cells are formed and in eight, ten or twelve days the excoriations are perfectly repaired.

It is not the importance of the affection which prompts the patients to seek medical attention, but the unceasing relapses, which cause great trouble.

In some cases the patient, having had suspicious intercourse, is greatly frightened from the possibility of a venereal or syphilitic lesion. Here comes the task of a physician to make his differential diagnosis between herpes and a venereal ulcer, or between herpes and mucous patches. This task, however, is simple and easy, so much so, that the doubt cannot remain long, when we consider the superficial character of the lesions, the arrangement of the excoriations in a round disposition (recalling the vesicles) in a word, the appearance of the excoriation has nothing to do with the neatly cut edges and with the ragged surface of the bottom of the venereal chancre.

I hardly believe that an excoriation from a little crop of herpetic vesicles could ever impose for an initial syphilitic lesion and the doubt cannot last long. Rather an eruption of superficial mucous patches in the internal sheet of the prepuce, or in the sulco balano preputiale, may be mistaken for herpes. Mucous patches, however, are much deeper, as they are true papules, and, furthermore, they are scattered in different places, while the herpetic vesicles, being very superficial, have a tendency to aggregate and coalesce together in little crops. Of course it will be found that mucous patches are associated with general syphilitic manifestations; but we must consider that herpes can be found in syphilitic individuals. In this case the general symptoms of syphilis will tell us that the patient is syphilitic, but will not help any in the differential diagnosis between herpes and mucous patches. It is rather important in some cases to determine the exact diagnosis between the two lesions. Furthermore someone has also advanced the theory that recurrent herpes progenialis has to be considered as a result of a syphilitic diathesis, which I strongly deny.

A very important question is whether the excoriations resulting from herpes may open the door for venereal or for syphilitic infection. In this case we find patients, who, having been infected on their usual herpetic excoriations, refuse to believe the physician, when establishing the diagnosis of an initial lesion, for the reason that they have been quite often subject to herpetic eruptions.

The question of herpes progenialis must be studied from the point of view of its origin, so that we may be able to stop its persistent relapses. When we speak of herpes, we mean a vasomotor trouble, which means an irritation starting from the genital sphere, which through the sensitive filaments of the nerves is carried to the ganglionic cells in isolated ganglia, or to the spinal cord, and, this irritation of sensitive nature is changed in those cells, and from them is carried to the nervous filaments, which regulate the tonus of the blood-vessels. In consequence a hyperemia is produced at the end of the nervous filaments which, followed by exudation, form the vesicles, which we call herpes.

It is possible that vesicles are formed on account of a local irritation as is occasioned in consequence of venereal excesses, neither would I deny the possibility of the staphylococci contained in the vaginal secretion, which in some cases may be the cause of the herpes. But these are not permanent causes, and if capable of producing an herpes once, could not consistently be considered as the permanent cause of the persistency in the relapses of herpes progenialis.

The cause, therefore, must be of a permanent nature. In the beginning of my practice I have

* Presented before the Second Annual Meeting of the American Urological Association, New Orleans.

limited myself to the enquiries of the patients, whether they had suffered any urethral affection, but the reply had been always negative, and I have remained in the darkness in reference to the etiological reasons. Gradually I have adopted the system of making a thorough examination of the urethra and from a large number of patients, who have applied for treatment of herpes progenialis, I have found in every case a condition of chronic posterior urethritis with all its complications.

I cannot refer to each of the single cases under my treatment, it would require a long and tedious report. I will limit myself to a few cases of the most striking character. A man in very good general health came to me for a fresh case of subacute anterior gonorrheal urethritis. This was his second time, some seven years previously he had been affected with another case of a severe nature, which had lasted over a year.

The anterior urethritis very easily yielded to the irrigation treatment with a solution of permanganate of potassium 1 to 1,000. He complained, however, that for years he had been constantly annoyed with herpes, and that as soon as the old vesicles had healed up, new ones kept coming. The examination of the urine showed a few shreds in the first beaker, and some more in the second. The shreds under the microscope resulted of mucine, with many mononuclear and a few polynuclear leucocytes. Some large pavimental epithelial cells, and some amorphous granules of sodium urate. The staining with aniline dyes did not reveal the presence of gonococci.

My diagnosis was that of a chronic posterior urethritis, remnant of the old attack.

In order to see whether any material alteration had taken place in the mucous membrane of the urethra, I passed an ordinary steel sound No. 12, which was easily introduced, but it showed some difficulty while withdrawing it. This was enough to give me the idea, that there was an infiltrated point in the bulbar region of the urethra, a kind of a wide stricture. In removing the sound a little drop of whitish fluid came out like we see in those cases.

For the purpose of washing and sterilizing the urethra I made a deep irrigation with the solution of permanganate of potassium 1 to 2,000. In letting out the solution a mass of thick mucus of stringy appearance came out from the urethra.

From the application of the instrument in the urethra, the patient suffered a recrudescence of the urethritis, and one day after an attack of fever. This of course required the intervention of internal remedies, and quinine was administered, which removed the fever, and cleared also the urine considerably. After a few days I resumed the irrigations with a mild solution of permanganate every two days, but no more mucus was seen. The patient had no more discomfort, and gradually was discontinuing the treatment. The most important feature in the case was that the herpetic eruption had not been seen since. Some three months after he came back with another attack of herpes in the internal surface of the prepuce. I repeated the irrigations with the Valentine apparatus, and after several attempts, another mass of mucus came out, of the same quality like that of the first time. For this reason I began the use of sounds regularly once a week together with the urethral irrigations. Neither the herpes nor the mucus appeared again. Lately his urethra could bear the introduction of No. 15 sound, which was passed once a month.

In my opinion I believe that in his urethra had been formed an enlargement in form of a cul-de-sac, above the bulb, and there some mucous secretion had found its receptacle. The sticky quality of the mucus, and its place, prevented the urine from removing it, by the act of the micturition, and in consequence it had accumulated to a certain quantity. The presence of the mucus, made more irritant by the urine and by its salts, was a sufficient cause to produce irritation on the sensitive filaments of the internal pudendi, and the herpes was the result. In nearly every case of recurrent herpes progenialis in the man, I have found the reason of its persistency in the altered condition of the urethra. In some cases herpes has had its reason of existence in the abnormal condition of the glands of the mucous membrane of the urethra. In some cases I have found the glands of Guerin affected. These two small glands, which are seated on both sides of the urethra underneath the fossa navicularis, have their excretory ducts near to the meatus. The gonococci sometimes find their way from the excretory ducts to the glands, which are affected with chronic inflammation. These glands in this diseased condition can be felt under the exploring fingers like two shots on both sides of the urethra near the frenulum. Although the urethra is nearly well, yet the patient complains of a kind of uneasiness, and an itching sensation near the meatus, toward the fossa navicularis, which compels the patient to squeeze that region, bringing out a little moisture, which relieves the itching. In consequence of this affection I have seen quite often crops of herpes progenialis around the sulco balano preputiale, and on the internal sheet of the prepuce, consequent to the irritation from the inflamed condition of these glands.

It is therefore necessary, in cases of relapsing herpes, to bring our attention to the condition of the urethra and of its glands, which quite often are the cause of the persistence of the herpes.

The pathological anatomy of the herpetic vesicles has not much interest, as it is the same which we find in any other vesicular eruption. It is an exudation of the serum of the blood from the capillaries of the papillary layer, with some mononuclear and a few polynuclear leucocytes, which effused in its meshes finds its way into the layers of the epidermis. The effusion of serum by its pressure detaches the horny layer of the epidermis, which being more resistent is raised up in round shape forming the cover of the vesicle. The size and depth of the vesicles depend

upon the intensity and degree of the hyperemia, which is the direct consequence of the vasomotor disturbance.

The local treatment of the herpes is very simple, usually washing with soap and water, and when dry, the application of absorbent powders, talcum, rice, oxide of zinc, bismuth, etc., afford good results. When there is some necrotic condition of the epithelial cells forming the bottom of the excoriation, I touch up the surface two or three times with a solution from 3 to 5 per cent. of nitrate of silver.

I do not advise the application of salves, which in the sulcobalano preputiale become altered and cause irritation, rather than benefit. I have seen that some physicians have resorted to the circumcision for the purpose of preventing the relapses of the herpes. This operation, however, has never been of any benefit whatever, the herpes instead of coming on the prepuce was coming on the glans and on the skin of the penis. In these kind of cases and for this purpose I consider the circumcision an entirely useless operation.

Pruritus.—Another reflex skin trouble is pruritus, which may affect the anus, perineum and scrotum. In most cases we find these regions affected with eczema, excoriations and rhagades. In these cases I consider the eczematous affection as a secondary one, produced mostly by the action of scratching and rubbing by the patient, in order to stop the itching sensation. The skin around the anus is red, swollen, thickened, like leather, showing excoriated places oozing serum, the folds around the anus are somewhat more pronounced, swollen and when the skin is distended rhagades are found. The irritation from scratching is often spread to the mucous membrane of the rectum causing a mucous discharge.

Those cases are usually diagnosed as pruritus and eczema. Often it is doubtful to which has to be given the precedence; both diagnoses are right, but I firmly believe, that pruritus is the first, and eczema is only the consequence of the wounds and of the irritation produced by scratching.

The cause of pruritus must be looked for in the condition of the urethra, and according to my observations the reason is found in the prostatic region. When the posterior urethra is affected, as a consequence the prostate is also swollen, enlarged and dilated. In many cases the urine is turbid, cloudy, sometimes contains shreds, long, stringy and tortuous, showing their origin to be from the follicles of the prostatic gland.

In these cases the examination of the urethra through a sound is necessary, to ascertain the presence of strictures, and it is also necessary to introduce the index finger into the rectum, to ascertain the condition of the prostate and of the seminal vesicles. In nearly all of my cases of pruritus I was able to find either both lobes of the prostate, or only one lobe, more often the right, swollen, thickened, or bulging up like a cyst. When the prostate is pressed, two or three drops of mucus came out of the urethra, which under the microscope contains the brilliant bodies of the prostatic glands. That mucus results of the chronic inflammation of the prostatic region, coming out of the follicles, is cause of an irritation, which affecting the sensitive nerve fibers, which so numerously surround the prostate, cause the itching sensation.

The nerves of the prostate and of the urethra proceed from the distribution of the pudendus internus, which forms an admirable network of nervous filaments. Moreover, the prostate is entered and surrounded by a plexus, which is known as the prostatic plexus, belonging to the great sympathetic system.

It is therefore clear that any disturbance of this region, affecting the different filaments of the sensitive nerves will be revealed with perversion of the sensitiveness (pruritus), and when affecting the sympathetic system will be revealed with morbid manifestations of the vasomotor sphere, erythema, formation of vesicles, herpes.

Sometimes the effect of the irritation does not remain limited to the locality, but it is carried through the nerve fibers to the spinal centers and from there up to the sensitive ganglia. These are the causes which we find quite often in cases of sexual neurasthenia. Cases of this kind come quite often under the treatment of the general physician, or of a neurologist as cases of simple neurasthenia.

It is my intention to limit my observations to the locality, and to the local pruritus, but I cannot neglect to mention cases of general pruritus proceeding from the same cause. A medical gentleman was under my care only a few days. He had a case of chronic prostatitis in consequence of a neglected blenorrhagia, and he was suffering with an intense pruritus of the anal and perineal region, which was relieved only by massaging the prostate. When he remained without treatment of the urethra and of the prostate, his sufferings were greatly increased, and the pruritus affected the backs of both hands, both arms, both feet and the calves of both legs. The itching was so troublesome, that the gentleman although he tried hard not to scratch, yet during his sleep scratched so severely as to produce deep and extensive excoriations. It is not entirely out the reach of an explanation the possibility of the generalization of pruritus not only, but also of an eczematous eruption, when we recollect, that the skin is a continuous involucre covering the whole body in connection with the mucous membranes, with innumerable vasal and nervous anastomoses. The prostate which is a glandular organ in intimate connection with the urethra, resembles somewhat a chestnut or a heart of the playing cards. It rests upon the aponeurosis mediana of the perineum and on the membranous portion of the urethra. Its upper portion, where the bladder rests is somewhat concave, and is intimately connected with the vesical tunics. Its inferior portion is connected with both deferent canals rest-

ing on the median line. The anterior portion of the prostate is in contact with the upper perineal aponeurosis, and the posterior is separated from the rectum only by the prostatoperineal aponeurosis, in consequence it is so easily felt by the exploring finger introduced into the rectum. It is an organ consisting of strong muscles and glands intimately connected with the posterior wall of the urethra, so that it is difficult to isolate the prostate from the urethra, which is firmly imbedded into its structure. The ejaculatory ducts, which are the continuation of the deferent canals go through the gland obliquely from backward to forward and from externally toward the middle, ending nearly together. The mass of glands forming the prostate ends in 10 or 12 excretory ducts, which open into the urethra on both sides of the verumontanum. In consequence of the spreading of the blenorrhagic process into the glands, we have only rarely cases of general gonorrheal prostatitis, which may end in an abscess with dangerous consequences. In the ordinary cases we have subacute or chronic prostatitis, which is noticed by the patient at the end of the micturition by a painful tenesmus at the time of squeezing out the last few drops of urine. Sometimes these last drops of urine are accompanied with thick mucus, or even with a few drops of blood.

Other times the process is much milder and the patient although annoyed by frequent micturition and sometimes also by night emissions, yet permits the thing to run without medical attention, alleging all the different explanations which the imaginative talent of the patient can only find. The inflammatory process, although of a catarrhal nature, increases the secretion of the prostatic glands, which sometimes oozes out in form of a sticky, clear albuminous fluid, as prostatorrhea, at other times on account of some difficulty to its issue is retained in the glands, causing their dilatation. It is in this way that we find the lobes of the prostate enlarged, and as I have already mentioned, to such an extent in some cases to give to the exploring finger a sensation like that of a cyst. I scarcely need to say that when the glands of the prostate are so inflamed and enlarged the surrounding connective tissues take a hand in this enlargement and in the congestion of the whole organ.

From the above considerations I find that pruritus of the perineum is explained by the irritation produced upon the sensitive fibers of the nerves, which are so abundant in that delicate region, from an accumulation of abnormal secretion, in the lobes of the gland.

Treatment.—It is easy to understand that the eruptions already mentioned or the pruritus will be of persistent character, as the anatomopathological alterations, which produce it are of a permanent nature. The massage of the prostate, or what is more often called the stripping of this gland, is of a great benefit for the reason of removing the secretion from the body of the glands, diminishing the distention. In consequence the massage of the prostate has been rightly recommended as the chief means to relieve this condition of chronic prostatitis.

I would not, however, rely entirely on this simple application, and I find that together external and internal applications are necessary. In my practice I cannot renounce to the irrigations of the entire urethra and bladder, through the Valentine apparatus, using a mild solution of permanagnate of potassium or biborate of sodium, repeated two or three times a week. In case of infiltration, or hardening of the mucous membrane of the urethra, the introduction of a sound covered with salve composed of 25 per cent. ichthyol in vaseline has given in many cases good results. This application, however, cannot be done more than once a week, and the operator must be cautioned that the prostatic urethra when inflamed quite often reacts very severely after one of these applications. For this reason we will advise our patient after the application of the fenestrated sound with ichthyol salve, to remain in bed for several hours, and in case of pains to apply hot water bag on the perineal region. To diminish the disagreeable tenesmus, the administration of the usual remedies as bromide of potassium, hyoscyamus, opium, trional, etc., come very handy and usually beneficial.

Locally the use of the ichthyol has given me the best results to stop the itching sensation and to heal up the results of the scratching, excoriations and eczema. I use my old liniment resulting of ichthyol, 3ij; aq. calcis, olii amygd. dulc., 3iv; aq. rosæ, glycerin, aa 3vj; m. f. linim. This is applied on cotton or English lint, and it is left on for the whole night, in the morning it is washed with a solution of carbolic acid, according to the following formula: Acid. carbolic., glycerin. aa 3j; aq. rosæ, alcohol. aa 3iij. M. ad us. Ext. as washing.

In case of complication of the mucous membrane of the rectum to the eczematous process, I advise my patient to use injections with a very weak solution of borate of sodium, at a warm temperature into the rectum twice a day, and by means of a speculum ani I introduce a small tampon of cotton saturated in 25 per-cent. solution of ichthyol in glycerin which the patient holds in, so long as he can. In my experience, ichthyol has an astringent action upon the prostate and on the vas deferens in case of its complication.

After the excoriations have healed up, and the eczema is improved, the itching sensation has also diminished, I advise the application of an ointment with oxid. of zinc, for instance, the modified formula of Wilson: benzoin, 5; vaselin, 70; zinc oxid, 25. When the skin has returned to the normal condition, the patient will finish his treatment, by bathing the perineum and scrotum with the carbolic acid lotion, and when dry, will cover the skin with rice powder or amylum. In case of presence of strictures, I continue the use of the sound for a long time, according to the feelings of the patient, and to the quantity of mucus, which

comes out after withdrawing the sound. Its application will be repeated every two or three weeks and also once a month, until no more mucus comes out after the application of the sound.

It would be tedious and perhaps useless for me to relate a description of a series of cases of the kind, where I have obtained satisfactory results with the mentioned treatment. I can only state that with patience and perseverance I have obtained with this method gratifying results in cases of many years' standing, cases neglected and left nearly to themselves without rational treatment.

THE TREATMENT OF SOME DISEASES OF THE EYE BY WARM MEDICATED SPRAYS.

BY DAVID T. MARSHALL, M.D.,
OF NEW YORK.

For the past year I have been making use of an old, but seemingly little known, method of treating certain diseases of the eye; namely the use of warm medicated sprays applied by means of a steam atomizer.

The method is simply this: a steam atomizer, such as is commonly used in spraying the throat, is filled with water, the alcohol lamp is lighted and a solution of the remedy indicated is put in the cup.

The patient is seated in front of, and close up to the atomizer, at such a level that his eye looks directly into the tube. When the spray is well started the lower eyelid is pulled down and the patient is directed to hold his eye wide open. The spray is directed alternately into one eye and then into the other, the duration of the treatment being from five to ten minutes. After spraying, the eye may be touched with bluestone or alum stick or applications of drops or ointment may be made as is indicated. These agents seem to act more effectively when applied immediately after the warm spray.

Cases of blepharitis marginalis heal with surprising rapidity after a course of spraying and yellow oxide or other ointment. As this disease is often complicated with, if not really caused by, a conjunctivitis more or less chronic and often trachomatous, it gets well because the conjunctivitis is healed at the same time. In practice it is very difficult to get blepharitis patients to remove the crusts from their eyelids. Unless this is done ointments do not act effectively. The hot spray softens the crusts and they may be removed while the spray is being applied. In this connection I may state that blepharitis cases often do better with ointments other than the classic yellow oxide. I have gotten good results with Lassar's paste, resinol ointment, boric acid ointment and even plain vaseline after yellow oxide in one-half- to one-per-cent. strength had been used for weeks, to no purpose. It is idle to scold the parents of the average clinic child because they fail to remove the crusts from their child's eyes. It is better to make use of a treatment which will cure the child's eyes in spite of the ignorance or carelessness of its parents.

Chronic conjunctivitis responds most satisfactorily to treatment with the warm spray. The spray is soothing and pleasant and patients enjoy taking it. Most cases of conjunctivitis do well under bluestone applied immediately after the spray. I apply it lightly to the lower lid and then let the patient bathe the eyes in a basin of cold water until the acute pain is somewhat abated.

Of all cases in which I have used the spray treatment, the most satisfactory have been some chronic cases of conjunctivitis and pannus, combined with more or less corneal infiltration due to old trachoma. We see many such in the dispensaries in New York. They are found principally among the poorer classes of Russian Jews, many of whom are tailors and work in poorly lighted and poorly ventilated sweat-shops. The plight of these people is sometimes pitiful in the extreme. They are compelled through poverty to work when their eyes are totally unfit to use. Some of them give a history of having had trachoma, with occasional attacks of pannus, for periods varying from five to thirty years.

Where the corneal irritation is due to the rubbing of roughened cicatricial surfaces of the eyelids, little can be done. In cases where the conjunctiva of the eyelids is swollen and succulent, the spray treatment, followed by applications of bluestone, is very effective. I have relieved a number of such cases, which had been treated with bluestone or nitrate of silver for months with no improvement.

Corneal ulcers and infiltrates often clean up rapidly under the spray treatment.

A method of treating chancroids by means of a weak spray of peroxide of hydrogen, applied by means of air at a pressure of 60 pounds to the square inch, has recently been suggested. I believe that a warm spray of a suitable solution applied with considerable pressure would favorably influence a corneal ulcer, but I never have tried it.

The pressure of the warm spray as it issues from the tube of the atomizer is practically inappreciable, but it cleans out an ulcer effectively.

Summary.—Spraying with warm medicated sprays is indicated in almost all diseases of the conjunctiva, as acute catarrhal, chronic, epidemic, gonorrheal, trachomatous and phlyctennular conjunctivitis; in diseases of the cornea as ulcer; infiltration and interstitial keratitis, and in iritis.

33 West Twelfth Street.

Isopral, a New Hypnotic.—Isopral, a chlorated propylic alcohol, forms a crystalline body readily soluble in water, alcohol and ether, and possesses a camphoraceous odor and aromatic pungent taste. Its physiological action has been carefully studied by D. Impens (Therap. Monatshft., Sept. and Oct., 1903), who finds that while less poisonous than chloralhydrate, it resembles this in action and is at least twice as efficient. Cardiac depression is less marked, respiration is only affected with tonic doses, and locally it possesses distinct anesthetic properties, though irritating at the same time. In doses of 0.5 to 0.75 gm. (8 to 12 grains), it is as efficient as chloral and it has no after-effects.

MEDICAL PROGRESS.

PHYSIOLOGY.

Mechanism of the Absorption of Cocaine Injected into the Spinal Canal.—The anesthesia following rachidian injections of cocaine, according to A. Valenti (Arch. Ital. de Biol., Sept. 10, 1903), is to be attributed exclusively to this alkaloid, which, remaining for a long time dissolved in the spinal fluid, acts locally upon the origins of the spinal nerves, paralyzing their sensory fibers. The secondary postoperative phenomena, analogous to those of acute cocaine poisoning, depend upon the toxic action of the alkaloid, which, on account of the late absorption by the lumbosacral arachnoid, passes very slowly into the circulation. It will require further researches to establish the fact, whether the very slow absorption of cocaine in these conditions, might not have a special influence upon the intensity of the toxic phenomena, which, following the hypodermatic injection of corresponding doses, seem to be less constantly manifested.

Macroscopic Modification of the Blood Preceding Coagulation.—A new phenomenon, visible to the naked eye, has been observed by V. Ducceschi (Arch. Ital. de Biol., Sept. 10, 1903) in a few drops of blood obtained from the finger-tip, and placed in the center of a watch-glass; after inclining the latter repeatedly at intervals of several seconds, and then holding it up to the light, there are noticed in the depth of the blood next to the glass a number of very fine whitish points or granules contrasting markedly with the blood. These appear within from forty seconds to two minutes after the blood is removed from the body, and rarely later. The granules usually have a diameter of from ¼ to ½ mm., and are no longer visible when coagulation sets in. Mixing the blood with an equal quantity of a one-per-cent. solution of ammonium oxalate prevents the formation of the granules. If the granulations be placed on a slide, dried in the air, fixed with a mixture of alcohol and ether and stained with one-per-cent. methylene blue, they acquire a diffuse blue color containing small prints of a deeper blue. The surrounding red blood cells have a greenish hue. Under the high power of the microscope, the bluish masses are recognized as clumps of blood-platelets, more or less altered, and of a smaller number of leucocytes whose nuclei stain much more distinctly than the platelets. If the granules be examined during the early stage of their formation and while they are rather small, it will be seen that there is little or no fibrin; the entire phenomenon, therefore, is one which precedes coagulation. If a beaker be nearly filled with the fresh blood of a rabbit, it will be observed that the granules form not only at the bottom, but also along the side, provided the blood be kept in motion by inclining the beaker several times; in blood which has been kept perfectly quiet the granules appear in but scant number. It is well known that the blood-platelets have a tendency to adhere to surfaces other than those of the normal wall of the blood vessels, and to gather in clumps. This phenomenon may be regarded as genuine agglutination, and is held by some authors as distinct, morphologically and physiologically, from coagulation. It will be interesting and perhaps of practical value in clinical medicine, to investigate the possible variations of the above phenomenon in various morbid conditions, inasmuch as a few investigators have observed marked oscillations in the number and even the complete disappearance of the platelets in various diseases.

Corpuscle of Poggi in the Hematopoetic Organs of the Premature Fetus.—Poggi deserves the merit, according to G. Zirolia (Arch. Ital. de Biol., Sept. 10, 1903) for having been the first to discover in the blood of anemics, a corpuscle which has the property of staining freshly with methylene blue, and which the discoverer regards as an immature element or one which has precociously escaped into the circulation. This belief is based upon the fact that the corpuscles of Poggi are normally found in large quantity in the bone-marrow, the seat of the manufacture of red-blood-cells. The author has demonstrated that they are also found constantly in the hematopoetic organs of the premature fetus of man and the other mammals. The presence of these corpuscles in embryos which have not arrived at maturity or which do not attain extra-uterine life, or which have lived but a short time in the uterus, in a small proportion in the bone-marrow, and in a large proportion in the spleen and liver, suggested to the author the thought that these are newly formed elements which have not yet arrived at physiologic maturity.

Gastric Glands Under Conditions of Lethargy and Activity.—In an investigation of the gastric glands of the marmot, with regard to their microchemistry the lethargy of winter and the activity of summer, R. and A. Monti (Arch. Ital. de Biol., Sept. 10, 1903) reached the conclusion that the delomorphic (acid) cells elaborate the hydrochloric acid in a very dilute solution, and eliminate it as rapidly as it is produced. This function is completely suspended during the lethargy of hibernation. On the other hand, the chief (peptic) cells elaborate pepsinogenic granules which slowly accumulate and are rapidly eliminated at the beginning of digestion.

Laws Governing the Secretion of the Aqueous Humor.—The physiological mechanism by which the aqueous humor is produced, resides, according to A. Angelucci (Archives Ital. de Biol., Sept. 10, 1903) in the parietal cells of the uveal capillaries. Section of the vascular nerves changes the function of these cells in such a manner that, at first, the lymph secreted is quantitatively diminished, while its chemical composition approaches more closely to that of the plasma of the blood. Strong electric and mechanic shocks imparted to the vascular fibres of the fifth nerve and the cervical sympathetic, produce nearly the same effects as division of the nerves; the albuminous content of the aqueous humor increases, and there is augmented intraocular tension. Lesions and irritations of the surrounding tissues, particularly of the cornea, and of the anterior part of the uveal tract during paracentesis, have the same effect as section and powerful irritation of the vascular nerves, increasing the quantity of albumin and imparting a fibrinous character to the aqueous humor. The above changes are attributed to the disturbance of the physiological equilibrium existing between the vascular nerves, the surrounding tissues and the capillary wall.

Transformation of Caffeine and of Xanthine into Uric Acid.—Caffeine and the other methylated xanthines are transformed in the animal organism, gradually losing their methyl groups, according to A. Valenti (Arch. Ital. de Biol., Sept. 10, 1903). The close affinity between xanthine and uric acid, brought to light by Fisher's research on the purin group, suggested to the author that possibly following the administration of caffeine, the xanthine group contained in the latter would be oxidized in the body into uric acid. If this be the case, then the higher methylated xanthines forming a considerable part of the diet of civilized people, in the form of tea, coffee and chocolate, might be considered as sources of uric acid. The author found that xanthine administered to a pigeon, is largely oxidized into uric acid, as has already been proved in the case

of hypoxanthine. He also found this to be the case with caffeine. This fact is of possible importance, for it affords a theoretical basis for the exclusion of coffee and its relatives from the diet of those subject to the uric acid diathesis. The author demonstrated that, at least in the ox, the liver is the seat of the transformation of large quantities of xanthine artificially administered.

Nature of the Physiologically Active Substances in Extracts of Nervous Tissues and Blood.—There are two groups of substances in watery extracts of nervous tissues, which, when injected into the veins of an animal, lower the blood-pressure, according to S. VINCENT and W. CRAMER (Jour. of Physiol., Nov. 2, 1903). Both of these are soluble in water and in normal saline solution (NaCl .9 per cent. in tap water). One group is easily soluble in absolute alcohol and the other scarcely soluble in this fluid. The alcoholic solution contains two depressor substances; one of them has its effect abolished by atropine, the other has not. The latter is the more powerful, but rather the less soluble in alcohol. The alcoholic solution gives an abundant precipitate with platinum chloride. Only a small part of this is readily soluble in water and on purifying gives octahedra and prismatic crystals. The greater part of the precipitate consists of potassium and ammonium platinum chlorides. The octahedra are the ammonium salts. The prisms have a platinum percentage of 32.8 corresponding to the platinum double salt of di-choline anhydride. The authors have not found any choline as such in brain extracts, but there is evidence that this substance exists in nervous tissues in the form above mentioned. The chemical and physiological tests recommended for choline in pathological blood cannot be relied upon; indeed, normal blood gives both the octahedra and frequently also the depressor effect.

Physiological Action of Betaïne Extracted from Raw Beet-Sugar.—In a series of experiments made with a different object in view, A. D. WALLER and R. H. ADERS PLIMMER (Proc. of the Royal Soc., Oct. 31, 1903) noticed that syrups made with ordinary beet-sugar had a faint cadaveric odor reminiscent of choline and neurine solutions, and the suspicion was aroused that the taint of the samples in question might be due to the presence of betaïne or of allied alkaloid. On investigation, Plimmer found this actually to be the case. In experiments upon cats and dogs they found that the hydrochloride of betaïne injected into a vein acts directly upon the heart and that commercial betaïne (Merck) is more powerful than betaïne extracted from beet-sugar. In all instances the mode of death has been by cardiac syncope from which no recovery could be obtained by artificial respiration. With sublethal doses the characteristic effect was a temporary fall of blood pressure, with a slight augmentation of the respiratory movements. It appears that betaïne in considerable quantity (3.75 per 1,000) is present in raw beet sugar.

Proteolytic Enzymes of the Spleen.—The most fruitful fields for physiological research to-day seem to be the domain of the various animal enzymes. S. G. HEDIN (Jour. of Physiol., Nov. 2, 1903) finds in the spleen of the ox two proteolytic enzymes, the one (α-protease) acting only or principally in an alkaline medium, and the other (β-protease) acting only or mainly in an acid medium. The β-protease can be obtained in solution by digesting the spleen with very weak acetic acid, and the α-protease (together with β-protease) by extracting the residue, with sodium chloride solution, dialysing and precipitating with weak acetic acid. The precipitate contains both enzymes. Both enzymes have been obtained in two forms: Combined with nuclein substances in which case they are not soluble in weak acetic acid; and not combined with nucleins, and therefore soluble in weak acetic acid. The form not soluble in weak acetic acid can be obtained from the soluble form by adding a nuclein substance and acetic acid in absence of salt. Ox-serum contains antibodies of the α-protease, but not of the β-protease. The spleen enzymes are in all probability contained in the leucocytes of the spleen, and there they may perform their functions. There they may affect the metabolism of the nitrogen inside the cells, and they may also have something to do with the digesting processes, which, according to the view of Metchnikoff take place inside these cells during the phagocytosis. As to the significance of the β-protease, it should be remembered that the acid reaction required for its activity according to investigations carried out by Ehrlich and particularly by Metchnikoff and his pupils occurs at some places inside the leucocytes. Thus the reaction of the nuclei is considered to be acid, and the digestion of bacteria and other substances taken up by the leucocytes in most cases takes place inside the so-called digesting vacuoles, where the reaction as a rule is acid. Whether the spleen enzymes may be active outside the leucocytes as well as inside is a question which cannot be settled at present. It does not seem to be impossible that the enzymes could leave the cells either by an act of secretion or perhaps by digesting some of the cells. Similar or perhaps identical enzymes seem to be present in several organs, although not in such amounts as in the spleen, and there may be proteolytic enzymes in the blood, although their activity may be checked by antibodies. Therefore, the author does not think that the spleen enzymes should at once be ranked with the so-called intracellular enzymes.

Proteolytic Enzyme in Ox Serum.—A weak proteid-digesting enzyme, acting in an alkaline medium, has been discovered in the serum of the ox by S. G. HEDIN (Jour. of Physiol., Nov. 2, 1903). The easiest way of obtaining it is to precipitate it together with a nuclein substance, *e.g.*, casein. Antibodies prevent the enzyme from acting in the serum. These are mainly contained in the albumin fraction. The enzyme may possibly be derived from the leucocytes in the blood or in other organs either by a destructive process, which might set the enzyme free, or by an act of secretion.

New Researches in Phosphocarnic Acid.—This phosphorized substance to which has also been given the name nucleone, is, according to A. PANELLA (Arch. Ital. de Biol., Sept. 10, 1903), a regular constituent of striated muscle, urine, heart, liver and kidney of various animals. The author has also discovered its presence in the brain. It is more abundant in the muscles of the rabbit than in those of the dog. It diminishes after death in direct ratio to the appearance and establishment of rigor mortis. After the latter has disappeared, the acid increases progressively with the commencement and course of putrefaction.

Action of Choline, Neurine, Muscarine and Betaïne on Isolated Nerve and Upon the Excised Heart.—A careful series of experiments was undertaken by A. D. WALLER and Miss S. C. M. SOWTON (Proc. of the Royal Soc., Oct. 31, 1903), with a view of comparing the physiological action of the above four members of the ptomaine group of organic bases. These substances are closely related, as the following formulæ show: Choline, $C_5H_{15}NO_2$; neurine, $C_5H_{13}NO$; muscarine $C_5H_{13}NO_2$; and betaïne, $C_8H_{15}NO_2$. The action of snake venom, diphtheria toxin and tetano-toxin was also investigated. Pure neurine non-

neutralized was found to be very toxic to nerve. Betaïne, as regards its direct effect upon nerve, is moderately active, *i.e.*, the electromobility of nerve, as evidenced by the negative variation of its current of injury, is abolished by betaïne and restored by subsequent prolonged immersion in physiological saline. Muscarine has a similar effect, but rather more pronounced. A comparison of the four substances was made by taking four nerves, as nearly similar as possible, and passing them simultaneously through each of the four test solutions and through physiological saline. The negative variation of nerve 1 immersed for seven hours in muscarine, was completely and permanently abolished. That of nerve 2, for seven hours in betaïne, was temporarily abolished. That of nerve 3, after seven hours in choline, was unaffected, and after twenty-seven hours diminished. That of nerve 4, in neurine for seven hours, was temporarily abolished and permanently diminished. Decomposed cerebrospinal fluid and decomposed serum-albumin temporarily abolished the negative variation of the nerve after an immersion lasting one and a half hours. Snake, diphtheritic and tetanus toxins also caused temporary abolition. Neurine, choline, muscarine and betaïne (as hydrochlorides) bring about diastolic arrest of the heart. The arrest thus produced is antagonized by the sulphate of atropine. Neurine and muscarine, in this respect, are more active than betaïne or choline.

A Few Reflections on Parthenogenesis.—A number of reasons which he thinks call into question the possibility of parthenogenetic reproduction of bees (*e.g.*, the development of the drones from unfertilized eggs), are advanced by E. Pflüger (Pflüger's Archiv, Sept. 23, 1903). The current teaching is that from unfertilized eggs there develop only drones; that the latter never develop from fertilized eggs; the drones can never reproduce male bees, but always have female descendants. The author interprets these statements as showing that the drones are only incomplete males whose testicle is endowed with but one-half of the necessary potency. He therefore concludes that the other half is present in the queen bee, which possesses the testicle necessary to reproduce males, and is, therefore, an hermaphrodite. In fact, hermaphroditism has already been observed in bees and butterflies.

Permeability of the Bladder.—Inasmuch as there has been a marked difference of opinion among investigators as to whether the wall of the bladder has any resorptive power, G. Fasola and G. Galeotti (Archives Ital. de Biol., Sept. 10, 1903) decided to explore this subject anew. Their experiments consisted in the injection into the bladder of dogs in which the ureters had been tied, of definite quantities of known solutions, and then measuring these after the lapse of a certain time. In other cases the vesical epithelium was beforehand altered by chloroform. They found that in the latter, the epithelium of the bladder acts as an inert semi-permeable membrane separating the blood from the contents of the organ. Across this membrane the osmotic equilibrium is soon established. There are no histological lesions accompanying the action of the chloroform employed, hence its effect is purely functional. In general, in the case of epithelium not acted upon by chloroform, the osmotic equilibrium is not established, and the vesical wall acts according to the physiologic necessities of the organism. In the case of hypotonic solutions, there is no variation either in volume or in concentration. With isotonic solutions there is no variation in the liquid injected if the animal has been well supplied with food and drink, but there is a partial absorption if the animal has been hungry or thirsty. In the case of hypertonic solutions there is a considerable absorption of sodium chloride. It follows that the bladder epithelium, at least of the dog, is permeable to either salt or water. The authors believe that the physiological significance of the resorptive power of the bladder with respect to sodium chloride lies in the fact that the organism finds it necessary to economize the chlorides: A great loss of this substance in a concentrated urine is obviated by its return to the circulation by way of the vesical wall. This permeability with respect to sodium chloride is a functional property of the epithelium of the bladder, a property which is suspended by the action of chloroform; for in the former case, osmosis occurs only one way, from the bladder to the blood, whilst in the latter case the osmotic flow is in both directions, leading to an equilibrium.

THERAPEUTICS.

Atropine and Hyoscyamine—A Study of Optical Isomers.—The relationship between the physical chemistry of various drugs and their physiological action is coming more and more to the foreground. A. R. Cushny (Jour. of Physiol., Nov. 2, 1903), finds that pure atropine and hyoscyamine act in the same way, and with equal potency on the central nervous system in mammals, and on the heart and terminations of the motor nerves in the frog. Atropine possesses a more powerful (stimulant) action on the reflexes of the spinal cord in the frog than hyoscyamine. The latter is almost twice as powerful as atropine in its action on the nerve ends in the salivary glands, heart and pupil. On the ground that the action of atropine is the resultant of the action of equal amounts of levo-hyoscyamine, the natural base, and dextro-hyoscyamine, these facts are interpreted as indicating that dextro-hyoscyamine has a more powerful action on the spinal cord than levo-hyoscyamine, while it has very little effect on the peripheral neurons mentioned. The examination of the action of dextro-hyoscyamine on these neurons proved this to be correct. Some organs have the power of differentiating between optical isomers, while others seem to be devoid of this power.

Strychnine in the Treatment of Sciatica.—At the present time we resort to many methods in the treatment of sciatica, such as massage and gymnastics, hydrotherapy, electricity, internal and external medication, is made without benefiting the patient in many of the cases, although here and there may be seen a case in which one or the other method of treatment may be useful. Th. O. Zarzyn (Roussky Vrach, Oct. 11, 1903) reports nine cases in which he resorted to the hypodermic use of strychnine, in 4 of the cases all the symptoms disappeared rapidly; 3 showed only considerable improvement, and this notwithstanding the very frequent injections of the drug; the other two were not influenced by the drug. The author is inclined to consider the hypodermatic employment of strychnine as the best method of treatment we have at present for sciatica.

The Action of Apocodeine.—This substance is an alkaloid obtained with some difficulty by the dehydration of codeine and it bears the same relationship to codeine that apomorphine bears to morphine, according to W. E. Dixon (Jour. of Physiol., Nov. 2, 1903). He finds that it very readily paralyzes nerve cells in exactly the same way as nicotine, but differs from the latter in that there is no initial stimulation. After the nerve cells have been paralyzed by apocodeine, nicotine on injection produces none of its usual effects such as rise in blood-pressure, vaso-constriction, etc., while the action of adrenalin remains unimpaired. As a result of this paralysis, arterioles dilate, blood-press-

ure falls, the heart beats more rapidly, and the automatic movements of plain muscle are all increased. Recovery is very slow. It is suggested that the increased peristaltic movements produced by the injection of many of the opium alkaloids and their derivatives is due to depression of the inhibitory sympathetic nerve cells. In a series of four of these alkaloids the purgative action varies directly with their paralytic effect in sympathetic ganglia. Reflexes are increased and strychnine-like convulsions are even sometimes seen. This is probably an effect on the sensory side of the cord. It is also suggested that nicotine directly stimulates the motor nerve cells in the cord, and that adrenalin diminishes resistance to impulses, especially in the motor side of the cord. Larger amounts of apocodeine paralyze the motor nerve endings in voluntary muscle like curare. The vagal endings in the heart are paralyzed as in the case of atropine. With still bigger doses after a preliminary stimulation, paralysis of vasomotor nerve-endings is produced. When this action is complete pilocarpine, physostigmine and adrenalin have no effect on the blood-vessels or blood-pressure, whilst barium and digitalis will still constrict the vessels and raise the blood-pressure. The effect of digitalis is, however, considerably diminished. The former three drugs therefore act on nerve-endings, and the latter two directly on muscle. The motor and inhibitory nerves to the intestines are paralyzed and, therefore, adrenalin and pilocarpine have no action. Other nerve-endings such as the hypogastrics are not affected, and adrenalin still produces its normal inhibition and pilocarpine some augmentation of movement. The accelerator nerve-endings in the heart are paralyzed. This effect is relatively easy to produce in the young animal. Adrenalin, caffeine and aconitine in large amounts quicken the normal heart, even when the vagi are paralyzed and it is profused artificially outside the body. After apocodeine adrenalin no longer accelerates, but caffeine and aconitine can still quicken. The latter two drugs, therefore, affect the heart muscle. The antagonism between apocodeine and either adrenalin or pilocarpine is on tissues, and is probably not the same as that between atropine and pilocarpine. On the intact animal apocodeine produces erection of the hairs over the face area and back, and edema of the face. The former effect is due to peripheral sympathetic excitation, the cause of the latter is doubtful.

Treatment of Chronic Interstitial Nephritis.—The effect of various measures upon chronic interstitial nephritis by quantitative control of albumin and estimation of blood-pressure, has been studied by P. Edel (Munch. med. Woch., Oct. 27, 1903), who comes to the following conclusions: Warmth and carbonated baths diminish both albumin and blood-pressure. The same is also true for rest in bed and inhalations of amyl nitrite. Exercise, especially climbing mountains, seems to have a very favorable influence; in normal individuals the pressure rises greatly, but in those afflicted with Bright's disease there is considerable dilatation of the vessels. The best results were obtained if the patients were allowed to exercise in the forenoon. Since albuminuria and increased arterial tension go hand in hand, it is likely that interstitial nephritis is directly due to a narrowing of the afferent vessels of the kidney. Neurasthenia constitutes an important etiological factor, and it would be a great mistake to condemn patients to muscular inactivity simply because they have a little serum albumin in their urine.

Treatment of Pulmonary Tuberculosis by Formaldehyde.—There are three different ways of administering formaldehyde in pulmonary tuberculosis. The first is by inhalation, the second by intravenous injection, the third by electricity. De Chowry Muthu (Brit. Med. Jour., Oct. 24, 1903), in discussing the first method, says that the idea that volatile substances inhaled are beneficial in consumption is as old as the Greeks. There are two ways of using inhalation, first by the ora-nasal inhaler, second by the vaporizer. The inhaler is pyramidal, flexible and light, made of perforated zinc and fits the chin accurately. He recommends a mixture of 40 per cent. of formalin, one part of chloroform, two parts rectified spirit, a few drops of ammonia are added to the mixture to neutralize the pungency of the vapor. The advantages of this method are, first, its simplicity, and the fact that the patient is able to use it in the open air or indoors at will, and second, that it prevents the inhalation of dust, and third, that the patient after leaving the sanatorium is able to effect this method of medication himself. The vaporizer consists of a spirit lamp with open boiler, into the mouth of which is let a tray which carries paraform powder with a little menthol for neutralization. The moist products from the decomposition of the spirit causes the evolution of the gas. The steam renders the action of the formaldehyde more effective and penetrating. This vapor bath is taken for an hour or two daily with the doors and windows partly closed. The advantages of this instrument are that the patient's room and its contents are rendered aseptic by constant disinfection, so that without practical doubt all expectorated tubercle bacilli are killed daily. Two conditions are necessary for inhalation to be efficacious. First, the inhaler must cover the nose; second, it must be continuously worn. To the statements made by many that these methods of treatment are futile, it is interesting to note that the state of the lungs of those engaged in dusty occupations has always shown that the inhaled dust penetrates far into the pulmonary tissue. Furthermore, if a volatile substance like chloroform can, when inhaled enters into the circulation, it does not seem reasonable to doubt that formaldehyde when inhaled, especially with chloroform and spirit, does not enter the alveoli. The writer has kept full records of more than 100 patients, and his conclusions are that these methods are a distinctly advantageous accessory to the open air treatment. The intravenous injection method is as yet *sub judice*. The writer commences the treatment with 50 c.c. of a strength of 1 in 2,000, increasing to 1 in 1,000. The patient often complains of numbness in the hands. The temperature sometimes rises slightly and sick headache and shivering fits are occasional. Dr. Rankin has injected 200 c.c. of 1 in 500. There was no result from this save a numbness at the tip of tongue. The objection to this form of treatment is that owing to the non-vascular character of the tubercular tissue, the formaldehyde cannot reach the affected part. It is, however, not intended to kill the tubercles *in situ*, the treatment being directed more to the lessening of the general septic infection than to a direct attack upon the tuberculous bacilli. As to the electric method, it is not as yet proven to be of service.

Vioform.—Vioform is preferable to iodoform, since it is a stronger antiseptic and deodorant without possessing the disagreeable odor of the latter. Large quantities may be introduced into the system without giving rise to toxic symptoms, and sterilization up to 140° C. does not alter its properties. It is inferior to iodoform in only one respect, in that it is unsuited for the conservative treatment of tuberculous joints. R Wehrle (Correspbl. f. Schweiz. Aerzte, Oct. 15, 1903, supplement) does not hesitate to state that it is a most valuable antiseptic.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

ERADICATION OF EXPECTORATION.

IN a pamphlet recently issued by the Chicago Board of Health on Suggestions for the Teaching of Cleanliness among School Children the first direction to the teacher is that children should be taught very emphatically not to spit—it is rarely necessary. To spit on a slate, floor or sidewalk is an abomination. It must appeal to everyone that this is making a beginning at the proper place. Expectoration in healthy children is a habit indulged in mainly because of bad example, and as the child is an imitative animal, perpetuated. As the Health Department's bulletin says "To too many children their one ideal is the hoodlum or street Arab who can squirt through his teeth."

Now that the crusade against tuberculosis is well under way a better idea of the dangers of expectoration is gradually becoming manifest. Last year, at the meeting of the British Medical Association, it was shown by a series of carefully prepared statistics that while factory workers were very liable to contract tuberculosis when there were many men employes among the number and some of them had tuberculosis, where the employes were exclusively female, there was much less danger. The reason is not far to seek and is evidently the habits of the two sexes in the matter of expectoration. Male employes are constantly subjecting their fellow-workmen to the danger of contracting disease by their habit of spitting around in all sorts of out of the way places where the expectoration becomes dried and gets into the air to become a source of infection for others.

That the immunity of working women in factories, where only women are employed, is not entirely due to their better habits as individuals—their avoidance for instance of alcohol and of exposure—can be understood from a second set of statistics which show that certain classes of working women, especially those who are employed in laundries and those who do duty as scrubwomen in large public buildings, are particularly liable to suffer from tuberculosis. In these cases the source of the infection is entirely attributable to the fact that these women are brought in contact with expectorated material on garments that have to be washed, or on the floors in the ordinary course of their employment.

Special effort should be made at school and also at the home to teach boys that they have no more right to expectorate than have their sisters. The lesson is simple. Very little insistence would secure its effective learning. This of itself, small as it may appear to be, would do more at the present moment than any other simple precaution that can be thought of to help in the prevention of the spread of tuberculosis. We as physicians should use all the weight of our influence to secure this advance in manners and the result will be evident before the rising generation is many years older.

LEGISLATION AND FIREWORKS.

AT a recent meeting of the New York State Medical Association a resolution presented by the Mississippi Valley Medical Association asking the cooperation of the medical profession in New York for the purpose of obtaining such legislation as will be necessary to prevent, as far as possible, the present list of casualties that occur every year on and about the Fourth of July in this country was unanimously adopted.

This movement has been taken up by many of the important medical bodies of this country within the last few months and promises to have a successful issue if medical men generally will interest themselves in presenting the subject properly to their legislators. Many State legislatures have just begun their annual sessions, therefore this is the appropriate time for physicians to bring their influence to bear and to furnish the

information necessary to make it clear how indispensable is legislation for the regulation of the present thoughtless but supremely harmful method of celebrating Independence Day.

The committee on Public Health of the New York State Medical Association are helping to distribute a pamphlet reprint from the *Journal of the American Medical Association* in which all the data necessary for a proper understanding of the awful mortality now usual at the beginning of July may be obtained. The last Fourth-of-July celebration caused the death or injury of nearly 4,500 persons. Among these 60 were killed outright, 10 lost the sight of both eyes, 75 lost one eye, 54 lost hands, arms, or legs, 174 lost one or more fingers and 3,670 received other injuries. Besides this fearful total there were over 400 deaths from tetanus which developed in wounds inflicted by fireworks on or around the Fourth of July. Many battles that are considered of great importance in history were fought without having a casualty list as large as this. No engagement of our Spanish-American War cost anything like so many lives or the disablement of so many of the combatants and the whole mortality and morbidity record of that war scarce equals in losses a single Fourth of July in deadliness.

There may be some doubt as to whether this is not an off year and whether, perhaps, there were not many more persons killed and injured than is usual. As a matter of fact, this is the first time in the history of this country that a complete list of the casualties incident to the Fourth of July has been made. Great care was exercised in the collection of the statistics and in the pamphlet issued by the *Journal of the American Medical Association*, the names of all persons who died from tetanus, with their residence, the circumstances of their wounding the special piece of fireworks that caused it and the termination of the case are reported.

No cases were accepted on mere hearsay and there was no accumulation of general statements from newspapers. In one large city where a newspaper reported 90 deaths only 10 were accepted in the statistics. The newspapers of Philadelphia stated that 500 people were injured in that city in connection with the Fourth-of-July celebration and that 380 received hospital treatment. The maker of the table could find definite details as to only 151 cases and these were the only ones reported. It is evident then that this table of mortality is eminently conservative in its make-up and that the injuries and fatalities must be accepted without any demurrer because of supposed lack of faithful investigation. Surely, with these facts before them, legislators will realize the necessity for passing stringent laws with regard to the sale and use of fire arms and all dangerous classes of fireworks for the Fourth of July.

Three classes of deadly weapons, as the events prove, are now in common use among the young people of this country, for the making of the noise necessary to show their patriotism. These are the toy pistol—the most deadly of weapons—the blank cartridge, and the giant firecracker. A determined effort must be made to do away with the permission now granted very commonly to sell such fireworks and borough and city ordinances will have to be amended so as to prevent their use. If this can be accomplished during the present winter there will be over 500 fewer deaths at the beginning of July and 5,000 families will not be called upon to suffer anxiety and discomfort because of the wounding of one of the members of the family during the senseless celebration of the "Fourth," when for one day the peace and health of the country are practically committed into the hands of children between four and sixteen years of age, while the rest look on and breathe a fervent prayer that nothing may happen, though they are sure that something is bound to happen to a great many of the participants.

In many places all that will be necessary will be for local boards of health to exercise the powers of guardianship of public health to secure the enforcement of legal regulations already existent but allowed to fall into innocuous desuetude. In others, new laws will be needed but their passage can surely be secured without difficulty if the present awful state of affairs is properly presented to the public and legislators.

OCHRONOSIS.

THE term ochronosis was first applied by Virchow to a remarkable pathologico-anatomical condition in which at autopsy nearly all cartilages of the body presented an intensely black discoloration.

Following his publication in 1866 five additional cases have been reported, viz., by Boström, v. Hansemann, Heile, Hecker and Wolf, and Albrecht and Zdarcek. In all of these "melanuria" was observed during life and in four the urine was black when passed. As regards the nature

of the urinary pigment Virchow suggested that this might possibly be a hematin derivative, while Boström, Heile and Hecker-Wolf regarded it as a melanin. Albrecht and Zdareck, on the other hand, although they were unable to isolate either homogentisinic acid or uroleucinic acid from the small amount of urine which was obtained at autopsy, express the opinion nevertheless that the melanuria may be referable to an alkapton acid or a corresponding derivative and suggest that the black color of the cartilage may then result through some interaction between an acid of this character and the common chondroitin sulphuric acid of the cartilage. In other words, they regard the ochronosis as the pathologico-anatomical expression of alkaptonuria.

Langstein recently has criticised the conclusions of Albrecht and Zdareck and has pointed out that the results of their chemical examination do not warrant the assumption that an alkapton acid was present in the urine. He communicates his own observations with reference to the urine of v. Hansemann's case, some of which had been preserved in a sealed glass tube. The urine reduced neither Fehling's solution, nor ammoniacal silver solution, and with ether no substance could be extracted which gave the alkapton reaction with a dilute solution of ferric chloride, viz., a momentary green coloration. All these reactions, however, were positive in the urine obtained by Albrecht and Zdareck. Like these observers, Langstein was unable to isolate either homogentisinic acid or uroleucinic acid, although these can readily be obtained with true alkapton urines, even when present in small amounts. As a further support to his conclusion that the melanuria in these cases is not referable to an alkaptonuria, he points out that in a true alkaptonuric, whom he was able to observe during many weeks, there was not noticeable the slightest discoloration of the cartilages of the ears.

In view of these contradictory reports, in which the diagnosis of ochronosis was only made at autopsy and in which altogether satisfactory examinations of the urine were not possible—in the one case only 20 c.c. obtained at autopsy were available, and in the other the urine had been preserved for several years in a sealed tube—it is interesting to note that in three undoubted alkaptonuric individuals observed in the United States the diagnosis of associated ochronosis could be made during life. A detailed report on this association may be anticipated at an early date.

ECHOES AND NEWS.

NEW YORK.

Illustrated Review of Physiologic Therapeutics.—This is the title of a most ambitious periodical published by E. R. Pelton, of New York. The first number, which is a quarto of 136 pages, is beautifully gotten up and the enterprise is worthy of the most active support. Dr. S. D. Morrell is the editor.

Christian A. Herter Lectureship.—The Faculty of the University and Bellevue Hospital Medical College announce the first series of Christian A. Herter Lectures, to be delivered by W. D. Halliburton, M.D., F.R.S., Professor of Physiology, Kings College, London, on "The Biochemistry of Nerve and Muscle." These lectures will be an extension of a course delivered before the students of the University of London; they will be illustrated by experiments and will contain the results of the lecturer's own physiological and pathological research. The course will begin on Monday, January 4, and will continue until Saturday, January 16, daily, at 4 o'clock, at the Carnegie Laboratory, 338 East Twenty-sixth Street. Those desiring reserved seats for the course will please communicate with Dr. E. K. Dunham or Dr. Graham Lusk.

Preventive Medicine Prize Essays.—The Maltine Company announces that after December 15 they will have ready for distribution the two essays on Preventive Medicine to which they awarded prizes of $1,000 and $500, respectively. They will be bound in permanent book form and will be sent by the company without charge to all physicians who request them. Address, The Maltine Company, Brooklyn, New York.

The Late Drs. Davison H. Smith, J. F. Chauveau, and David Franklin.—At a meeting of the Medical Association of the Greater City of New York, held December 14, 1903, the following report was received and adopted: It is with profound regret that your committee record the sudden and untimely death of Dr. Davison Heermance Smith, a member of this Association and the son of its esteemed President. The subject of this sketch was born in New York in June, 1875. After a suitable preparatory course of study he entered the academic department of Columbia University, receiving in due course the degree of B.A. From the medical department of the same university he was graduated in 1902, and soon afterward he was admitted to the House Staff of the New York Post-Graduate Hospital. It was in this institution that his death occurred from surgical shock, the result of a painful operation, bravely met, that was undertaken for the relief of mastoiditis. Possessing a genial and generous disposition, he endeared himself to a large circle of friends, and, though only on the threshold of his professional career, he gave promise of early success in a manifest zeal, earnestness of purpose, and faithful regard for duty. On behalf of this Association the Committee extends to the bereaved family of the deceased assurances of the inexpressible depth of its sorrow and sympathy in their affliction, and furthermore recommend that appropriate notice of his death be entered in the minutes of the Association and that a copy be transmitted to his family. (Signed) J. Blake White, P. Brynberg Porter, Wm. Seaman Bainbridge.

At the same meeting a report of the Committee on the death of Dr. Jean F. Chauveau was presented, which was in part as follows: A few months ago he celebrated the fiftieth anniversary of his entrance

to the medical profession, an occasion which prompted the affectionate congratulations of a large number of friends who had learned to value the kindness and gentleness, as well as the wisdom, with which he always met the requirements of friendship and professional loyalty. (Signed) A. B. Judson, A. B. Ball, F. E. Sondern.

Also a report of the Committee on the death of Dr. David Franklin, the concluding portion of which was as follows: Of him it may truly be said, medicine was his religion and his politics, his happiness and his misery. He was of unimpeachable honor and integrity. He had the gentleness of a woman and the nerve of a man of steel. He was keenly observant and of wonderful patience and endurance. He was beloved by his friends and adored by his patients.

Resolved, That this Association express by a record on its minutes its deep sense of loss in the death of Dr. Franklin, and that a copy of these resolutions be sent to his family, together with an expression of the Association's profound sympathy. (Signed) Samuel M. Brickner, Edward Fridenberg.

Opium at Auburn Prison.—It is said that through the connivance of certain officers at Auburn prison the convicts there are being daily supplied with opium. The opium evil is one of the worst with which prison officials have to contend. The officers are constantly in fear of the possible act of some opium-crazed convict, who frequently attempts murder for some real or imaginary wrong. As a result of Warden Mead's investigations, one officer has resigned and other resignations or dismissals are expected. Locked up in the warden's office at the prison is a bag of innocent-appearing English walnuts. They came about Thanksgiving time addressed to a convict. An officer with a keen scent thought he detected the smell of opium, and cracking one of the nuts found enough inside to satisfy the craving of an opium fiend for some time. Opium has been found frequently rolled up in tinfoil in bottles of mustard pickles. The officers have constantly to be on the lookout for this sort of thing. The physicians are under instructions to keep a close watch to see if any of the men are using it.

Eastern Medical Society of New York.—This society has engaged permanent quarters at Clinton Hall, 151-153 Clinton Street, New York. Possession will be taken on or about January 1. The building will offer every facility of the modern clubhouse, all of which will be open to the members. A reference library is one of the projected features of the society. At the annual election, held recently, the following officers were elected: President, Dr. Louis J. Ladinski; 1st vice-president, Dr. David Robinsohn; 2d vice-president, Dr. Tobias Berger; treasurer, Dr. Joseph Barsky; corresponding secretary, Dr. Abr. L. Wolbarst; recording secretary, Dr. A. J. Ronginsky. Dr. W. Freudenthal was elected trustee for three years. The chairmen of the new committees are: Committee on Ethics, Dr. A. A. Himowich; Committee on House, Dr. E. K. Browd; Committee on Admission, Dr. John A. Price; Committee on Library, Dr. Charles Rayevsky.

PHILADELPHIA.

Physician Seriously Injured.—Dr. George I. McLeod, Jr., of Ardmore, was badly injured on the evening of December 16 while trying to board a moving train at that place. Both feet were so severely crushed that they had to be amputated later at the Pennsylvania Hospital, where the patient was taken. He is now doing well and recovery seems assured. Dr. McLeod served in Porto Rico during the Spanish-American war and last year distinguished himself at Ardmore by abandoning his practice to care for smallpox patients at that place.

Scientists to Meet in Philadelphia.—On December 29, 30 and 31, the annual meeting of five affiliated American scientific societies will be held at the University of Pennsylvania. The Association of American Anatomists will meet in the Wistar Institute; the Society of American Bacteriologists in the Laboratory of Hygiene; the Society for Plant Morphology and Physiology in Biological Hall; the American Physiological Society on Tuesday in Medical Hall, and on Wednesday at Jefferson Medical College, and the American Society of Zoologists, Eastern Branch, in Biological Hall.

Advantages of the Marine Hospital Service.—"Advantages Offered by the Public Health and Marine Hospital Service of the United States to Recent Graduates in Medicine" was the title of an address given to the students of Jefferson Medical College December 16 by Surgeon-General Walter Wyman. The speaker was the guest for the evening of the H. A. Hare Medical Society of the college. Dr. Wyman said that the principal features of the Marine Hospital service were not generally understood. After mentioning many of the facts regarding its organization he stated that there were 22 national marine hospitals and 121 relief stations. In them are treated annually 56,000 seamen. Continuing, Dr. Wyman said: "I know of no medical service in the world that holds out the same facilities for the professional advancement of its officers. It has at least fifteen expert bacteriologists. It offers opportunities and encouragement for continued study, free from the petty annoyances and interruptions of private practice. It keeps its officers supplied with the latest books, instruments and apparatus, beyond the reach of many recent graduates. Aptitude and ambition to excel in any branch of medicine, surgery or preventive medicine have in it their full chance of fruition. The service has a fine record and a brilliant future—and it is free from politics."

CHICAGO.

Report of Illinois State Board of Health.—The Secretary of the Illinois State Board of Health, Dr. James A. Egan, Springfield, has just issued a report on medical education and an official register of legally qualified physicians. The book contains a list of the city, district, and county medical societies; a list of the Chicago Medical Colleges, and their faculties; a summary of the laws and regulations governing the practice of medicine in the United States and territories of the Union; a list of the medical colleges in the United States, and a summary of the decisions of Illinois courts of interest to physicians. It is a book of nearly 600 pages; it is well printed, and reflects great credit on the Secretary of the Board, upon whom devolved most of the work in its preparation.

How Crime May Be Prevented.—This subject was discussed by Judge Richard S. Tuthill at the monthly dinner of the Marquette Club recently. Among other things, the Judge said: "There has been no improvement in 500 years in treating criminals. There is some modification in punishment, but the main idea is to punish the criminal. Punishment is not the only remedy. Adults should be punished, but the way to prevent crime is to teach the children that the police, the judge and the law are not their enemies. Criminality is a disease. If it has developed in the boy beyond cure, send him to an

isolation hospital for from one to three years, where he will have good men and good women to help him with their advice. The child criminal," continued the judge, "began with staying away from school. Then the boy who had to have amusement would patronize cheap theaters, and to go there had to steal. Then came the criminal court, the jail, and the bridewell, where he was graduated in crime through the agency of the State."

Reappointment of Dr. Reynolds.—Commissioner of Health Arthur R. Reynolds was reappointed by Mayor Harrison on Dec. 14, and his appointment confirmed subsequently by the City Council.

Reduction in Diphtheria Mortality from Antitoxin.—The health department states that since the introduction of antitoxin in the treatment and prevention of diphtheria, its mortality-rate has been reduced by nearly one-half—that is, from an annual average of 6.25 deaths in every ten thousand of the population in the seven years, 1889-1895, to an annual average of 3.24 in the seven years, 1896-1902, of antitoxin treatment. But this is not enough. The seven years' experience clearly proves that no child should or ever did die of diphtheria when treated early enough with a sufficient quantity of good antitoxin. The pre-antitoxin mortality of diphtheria in Chicago was about 35 deaths in every one hundred cases of the disease. In the many thousands of cases among the poor and destitute treated by the department inspectors under the most adverse conditions, the rate for the whole number has been less than seven deaths in the one hundred cases. There are many physicians in Chicago and elsewhere who have records of hundreds of cases with a rate of less than two deaths per one hundred.

GENERAL.

Resignation of Dr. Goelet.—Dr. Augustin H. Goelet has resigned the Chair of Gynecological Electro-therapeutics in the International Correspondence Schools of Scranton, Pa., to take effect Jan. 1, 1904.

Vaccination for Railway Men.—The Pennsylvania Railroad Company on December 16 issued orders compelling all employes to be vaccinated. Dr. W. K. Shaw, local medical examiner, who has charge of the work in the Pittsburg Division, began at the Union Station. All trainmen were vaccinated, and with a corps of assistants the vaccination of the men at the Pitcairn shops was begun. All the local shops will be visited and no employe will be overlooked.

Index Medicus.—This valuable publication has now some 450 subscribers—a meager list and unfortunately a commentary on bibliographical scholarship. We learn that there is every reason to believe that, if 500 bona fide subscribers can be secured, that the Carnegie Institute will continue its appropriation and make the *Index* a permanent affair. American physicians should not rest under the imputation that there are only 500 of its 120,000 practitioners who are up and alive to the interests that the *Index Medicus* represents. There should be thousands of active, wide-awake men in this country ready to support the *Index*. American physicians are proud of their institutions. Surely the extent of this is not measured by a paltry $5.

Cause of Butler Epidemic.—Dr. George A. Soper, a sanitary expert, engaged by *The Engineering News* to investigate the typhoid epidemic at Butler, Pa., and its causes, reports that the epidemic has by no means attained its culmination, about 50 per cent. of the cases not having reached the critical stage. The epidemic he attributes to the suspension of the mechanical filtration of the city water supply. In three weeks there were 1,000 cases, and up to December 14, 1,247 cases and 51 deaths had been reported. Announcement was made December 15 that Andrew Carnegie had donated $5,000 to the Pittsburg typhoid fever aid fund.

Southern Medicine.—Dr. W. E. Fitch, the founder, and for many years editor and business manager of *The Georgia Journal of Medicine and Surgery*, published in Savannah, Ga., has sold his interest in the publication to his former associate and co-editor, Dr. St. J. B. Graham, who now becomes editor and sole proprietor. The name of his new venture is *Southern Medicine*.

A Museum of Security.—The American Institute of Social Service has been holding recently a series of meetings at the United Charities Building, 105 East Twenty-second Street, relative to the establishment in New York of a museum of security. The plan proposed is modeled after that of the Association of Industrialists of France. Such an institution would contain not only models of devices to prevent accidents, but also exhibits of means to improve hygienic conditions. As a result of its establishment on the Continent statistics show, or seem to show, that in Germany during a given period the fatalities numbered proportionately only one-fifth of those in America, while in Austria the proportion was even smaller. In support of argument favoring a closer study of accident prevention, Rev. Dr. Josiah Strong, the well-known sociologist, speaks as follows: "During the last five years there have been 38,890 killed on the railways of the United States. The injured in the same time have numbered 253,823. So the daily average of killed has been 21 and of injured 139. From these statistics it is seen that there are in this country to-day 51,882 persons who are condemned to death, to be executed on the railroads, within the next five years, taking into consideration the increase in travel. And you must remember that thousands of others are being killed in mines, factories, and building operations. John Mitchell tells us that two men die of injuries in the Pennsylvania anthracite mines every day."

While the facts here cited would seem to be conclusive proof of a woful lack of safety appliances, it appears to us that conclusions drawn from them are inadequate as a basis for the establishment of a security arsenal in this city. The death rate might be decreased somewhat, but it is not taken into account that a majority of accidents to life and limb are the direct result of gross carelessness on the part of their victims; and, in spite of all that might be done in the direction proposed, such decrease would not be commensurate with the efforts either of inventors or philanthropists. Humankind has never been quite able to see why, if conditions were thus and so, it might not be made to live forever, and consequently the imaginary draught from "fountains of youth" is always very refreshing and is always just on the point of merging into a real and actual potion. It is a curious fact that the death rate the world over holds about the same ratio to the birth rate year after year in spite of artificial devices on the part of man and of devastating disease on the part of nature. Let us safeguard ourselves in every reasonable way, let us fight abnormal influences in our lives whenever possible, but when comes the inevitable hour let our passing be quiet and without fear.

End of One Anti-drug Movement.—The so-called anti-drug movement in which some of the best-known New York clergymen were interested has

come to an end through its connection with a quack medical concern. Annoyed at the manner in which it has been advertised in newspaper stories, the International Committee organized for the suppression of drug addiction, has dissolved, with a declaration that not one member had profited to the extent of a single cent through his connection with the work. It was also stated in the preamble of the resolution that contributions, despite many public appeals, have not been sufficient to carry on the benevolent part of the work on an extended scale. "Confusion has arisen in the public mind from the mingling of a charity with a purely business enterprise, and there is difficulty in separating the two, and this committee stands sponsor for its business as well as its benevolence in sight of the world" are the closing words of the preamble.

Obituary.—Dr. Francis W. Higgins died suddenly at Cortland, N. Y., December 18, of heart disease, aged forty-six years. He was President of the Third District Branch of the New York State Medical Association and Vice-President of the State Medical Association.

CORRESPONDENCE.

"DISAPPOINTING THE DOCTORS."

To the Editor of the MEDICAL NEWS:

DEAR SIR: The editorial article in your issue of today very justly takes the Charity Organization Society to task for the ill-considered title which it has used for one of its Short Stories. While we shall try to make amends, as you suggest, in the editorial columns of *Charities* we should like, also, to trespass upon your space so far as to give the title its deeper meaning.

The cure of tuberculosis has for so long been thought of by charity workers as an almost hopeless task that we felt a genuine joy when our Society saw itself becoming an adjunct to the successful physician in the treatment of the dread disease. And when, as in this instance, our agent not only furnished good food and medicine, but also good cheer, spurred the patient's ambition and nurtured her hope of recovery, a hope which a number of physicians did not share, we may, perhaps, be forgiven for becoming unduly jubilant.

We are well aware that doctors are not disappointed by the restoration of the sick to sound health, and to give a true history of the successful cure of a consumptive patient in which physician, nurse and charitable worker all participated as an instance of how we are disappointing doctors, was, of course, distinctly unfair. It should, perhaps, have been entitled "The Story of How we are Disappointing the Grave." It is undoubtedly understood by everybody concerned, that the title was not intended to be taken literally but was formulated for the innocent purpose of catching the eye of a reader. It is of a class with the remarks not infrequently heard, implying that lawyers are disappointed when equity and justice prevail without expensive law suits; that doctors are in clover in times of epidemic or that representatives of organized charity prefer seasons of industrial depression and hard times. All are alike unjust and alike in questionable taste.

Will the doctors please accept our sincere apologies?

Sincerely yours,

New York, Dec, 21, 1903. EDWARD T. DEVINE.

Severe Grip.—The grip is particularly severe in New York City this winter, and pneumonia is a frequent and severe complication.

SOCIETY PROCEEDINGS.

SOCIETY OF THE ALUMNI OF CITY (CHARITY) HOSPITAL.

One Hundred and Eighth Stated Meeting, October 14, 1903.

The President, D. E. Walker, M.D., in the Chair.

Periodical Rise of Temperature After Miscarriage.—Dr. Potter said he saw three weeks ago, at what would have been the fifth menstrual period, a young woman in her first pregnancy had an attempted miscarriage. She first noticed, after getting up in the morning, that her night clothes were blood-stained, and she had pain. He was informed over the telephone of this condition by the husband. He adopted the usual treatment, and the pains stopped. The cervix at no time was very much dilated, and there was no further appearance of the hemorrhage. He made one vaginal examination, using rubber gloves, which had been boiled in a solution of lysol. Two days later the temperature went up to 104° F. A small dose of calomel and tincture of aconite was given and the temperature fell to 99° F. Three days after that there was another rise of temperature. The lungs were normal. In examining the patient this time he noticed a small boss in the first lumbar vertebra, but there was no history of any pain in the back nor difficulty in stooping over; nothing referable to Pott's disease when a child, and there was no pain around the eminence in the lumbar region. There was a slight pain in the lower iliac region of the left side, which was relieved by turning on the right side. That was relieved and temperature became normal. Several days later the patient being practically well, and walking around the room, the temperature again rose to 103.8° F., with no local symptoms. The blood had been examined five or six times for malarial plasmodia, but none had been found. Three physicians have seen the case, and none of them has made a diagnosis. The first physician who saw the patient in consultation never suggested the possibility of a general infectious disease. He thought it was due to the miscarriage—that is, pus somewhere in the pelvis. The surgeon who saw the case five or six hours afterward, at the request of the family, threw out any possibility of trouble in the pelvis. He said he could find nothing there, and thought the case was typhoid fever. She had typhoid fever five years ago. It certainly was not a typhoid temperature, and there was no Widal reaction. The urine had no albumin, no casts, but a few pus cells; sp. grav. was 1.018; reaction acid. Leucocytes at time of second attack were 12,000.

Dr. M. Manges said with reference to second attacks the facts are clearly stated by Kussmaul. Of his 1,000 cases 2¼ per cent. had two attacks. The interesting feature about second attacks is this: That the susceptibility to a second attack is greatest within the first year, is less in the second, and diminishes up to the fifth year, but a second attack may occur at any time. He had a patient who had had three distinct attacks during her life. She is thirty-four years of age, and he thought the diagnosis in each attack was unimpeachable. At the Mount Sinai Hospital second attacks are met with, but the point is, in the first five years one is most susceptible to the reinfection.

Adherent Pericardium.—Dr. Morris Manges presented a case of exophthalmic goiter, which was first admitted to the Mount Sinai Hospital some seven years ago, and entered the Ophthalmic Division on account of the marked exophthalmos—that being so marked that a corneal ulcer had developed near the outer canthus of the eye, the evidence of which you see. A double

canthotomy had to be done at that time. One sees the evidence of the corneal ulcer and where the palpebral fissure has been lessened. Dr. Manges called attention to the unique pulsations in the epigastrium, the condition of the apex beat and some of the phenomena that accompany an adherent pericardium. He also has a moderate hypertrophy of both ventricles and a slight systolic murmur. There is no history pointing to an adherent pericardium, but that need not deter one from making the diagnosis, because it is not an infrequent occurrence to find an adherent pericardium, where there is no history of pericarditis. One should bear in mind that cases where pericarditis has existed may occur without subsequent evidence of pericardial adhesions. Dr. Manges remembered one case in particular, where a boy with a purulent pericarditis was operated on, and 75 ounces of pus was removed. That boy within four months afterward became a District Telegraph boy, and although this pericardium is absolutely shut off as a result, there is absolutely no clinical manifestation of the condition. In the epigastrium and in the region of the apex beat there is an interesting series of "pulsations," which are changed in association with the respiratory movements. At the end of inspiration the movements are much more marked, and at the end of expiration they are less marked, all of which changes are due to the movements of the diaphragm. Broadbent's sizes can also be demonstrated in the posterior scapular line of the ninth, tenth and eleventh spaces—with each systole there is a retraction. For this one needs a good side light, and it is to be explained in the same way as the retraction in the epigastrium is.

This patient has not the paradoxical pulse, the venous phenomena in the neck or the first rib sign. This epigastric sign is not usually described in text-books on this subject. The case in that respect is a unique one. Cases of adherent pericardium are much more common than are supposed. The X-ray examination was very useful in corroborating some of these facts.

Dr. D. H. Wiesner said that the eye symptoms mentioned, and the condition present, are interesting. It is also a very unusual case. It is very seldom that one gets an adhesion of the two lids—anchyloblepharon—as in this case, after a cantholysis. The fact of the cantholysis being necessary, of course, would indicate the extremeness of the case.

Renal Calculi; Nephrotomy and Nephrectomy.—Dr. A. Lyle presented this case. Mrs. D., Italian, thirty years of age, entered the hospital June 29, 1903. Family history negative. Present history: Two months ago gave birth to a child, and since then has had severe pain in right lumbar region—pain being transmitted forward and downward to inguinal region. Had chills, fever and night sweats. On examination temperature was 105° F., pulse 130. Palpation revealed an oval hard mass in the kidney region, while the abdominal muscles on the same side were hard and tense. Patient complained of severe pain on pressure of the right abdominal muscles, as well as on the bimanual pressure. The patient was put to bed for observation. Urinary analysis showed sp. gr. 1.010, alkaline, moderate amount of albumin, pus, blood and renal epithelium. For three days temperature ranged between 101° and 104.5° F. Diagnosis of renal calculi with pus was made. On July 2 an aspirating needle was introduced into the right kidney under cocaine anesthesia, and pus evacuated. Ether was at once given, and a lumbar incision made over the kidney. Patient's condition was critical and extreme haste was made necessary. The bleeding points were controlled by gauze packing, and the kidney was incised longitudinally through the cortex into the pelvis. Several small abscess cavities were opened and four calculi removed. The anesthetic had to be discontinued before the pelvis of the kidney was reached and free stimulation resorted to. The wound was tightly packed with plain sterile gauze and the patient returned to bed. The temperature dropped that evening to 100.5° F., and the pulse to 120. The following morning the temperature was 99° F., and the pulse 112. She rallied remarkably well from the operation, but the temperature ran high, varying between 99° F. and 102° F., or at times 104° F. Nephrectomy was advised, but persistently refused, until patient was in almost a moribund condition. On August 6, with temperature 102.8° F., pulse 120, the patient was again put under ether, but before anesthesia was complete the heart fagged and the anesthetic was discontinued—a hurried dissection of the kidney with the finger was made until all adhesions were freed. The patient being in a moribund condition, no dissection of the vessels was made, but two large pedicle clamps were made to grasp the vessels and ureter. The kidney was removed, the wound packed with gauze and the patient returned to bed, the whole procedure being completed in five minutes. Saline infusions and other free stimulation served to tide over the critical moments. The convalescence was uneventful, and the patient was discharged on August 30, 1903.

Dr. F. M. Jeffries reports on the specimen as follows: "Multiple abscesses, acute and chronic interstitial nephritis. Parenchymatous degeneration. Acute and chronic glomerular nephritis. Calcareous degeneration and numerous casts."

The Relation of Proteids to Edema in Mirantic Children, with Urinalysis in Infantile Diarrhea.—Dr. Potter A. Palmer, of East Orange, N. J., read this paper. Will be published in a subsequent issue of the Medical News.

Dr. W. L. Baner, in discussing Dr. Palmer's paper, said that one not infrequently finds infants with severe diarrhea, who have a considerable amount of edema, and the urine does not show anything, and one is in doubt about what to do. The edema certainly seems to come in some way from the inanition of the child, and it is therefore quite a problem just how to adjust the food, so as to increase nutrition without increasing the diarrhea. In Dr. Potter's cases the dropsy was invariably due to inanition—what might be called an inanition edema—but there are some cases in which there is an acute nephritis, secondary to the dysentery. He had in mind two cases, giving the agglutination test with the Shiga bacillus in which albumin, casts and blood were found in the urine. In one case the toxemia was very severe. The suppression of urine became complete in that case. The second case had a favorable termination, and the urine cleared up after the dysenteric symptoms disappeared. In regard to the question of edema being due to inanition, he remembers the case of a man who fasted forty-five days some years ago, and was much troubled toward the end of his fast with edema of the ankles and feet, so that he could hardly get on his shoes. His urine was normal. No blood examination was made in his case to see if there was hydremia, but there seemed to be some distinct connection between the inanition and the edema.

Dr. A. Lyle said, in reply to Dr. Reilly, that there was no examination made of the other kidney. He felt satisfied from the patient's general condition and the condition he found this kidney in when doing the nephrotomy, that there was no function being performed by this kidney, and the temperature that the patient ran afterward being so septic, it was decided to

remove it. With regard to the length of time the clamps were left on, he left them on for forty-eight hours. He had no idea how long they should be left on.

Dr. R. Guiteras congratulated Dr. Lyle on removing the kidney in five minutes on the second operation, because in a great many of these cases of calculous nephritis there is so much sclerosis of the kidney and so many adhesions that it is almost impossible to remove it in any time. The upper leaflets of the perirenal fascia in such cases are principally involved, and the adhesions to the diaphragm or to the vena cava may be so firm as to render the removal of the organ impossible. Very often when a nephrotomy is performed in a case of this kind and all the stones are not removed sometimes one cuts into an abscess cavity or the pelvis of the kidney and evacuates the pus, feels no stones, but afterward if the kidney is removed one will find a stone in some part of the kidney communicating with the abscess cavity. Another interesting feature in this case was the leaving on of the clamps. In two cases Dr. Guiteras has left them on after nephrectomy. The first time for four days. He presented that case before the Genito-Urinary Society. There were a number of general surgeons present, who discussed the case, and no one had had the experience before of leaving on clamps, and could not state just how long they should be left on. In the other case he left them on for four days, but in reading over the literature of the subject afterward he found that a French surgeon had left clamps on only forty-eight hours, while another one left them on but twenty-four hours, and there had been no hemorrhage following their removal.

Dr. J. R. Goffe said the case seems to speak for itself. Cases of a similar pathological condition are, of course, not uncommon, but the dexterity and rapidity with which the operation was performed is rather unique. During the last year at the Polyclinic he had a case of stone in the kidney that had been diagnosed as an ovarian tumor. There was a large tumor that reached from the site of the kidney into the pelvis and was fluctuating, but he was able to differentiate by careful examination between the pelvic organs and this tumor, and following it up, he made up his mind it was a kidney. After making a posterior lumbar incision he evacuated an immense quantity of pus from the kidney, and found a large stone in the pelvis of the kidney blocking the mouth of the ureter. The woman was not in such a precarious condition as the patient spoken of to-night. A nephrotomy was done at the time. After evacuating the pus (it was a multilocular affair), the kidney was dissected out and removed. The patient recovered. She had been treated for malaria for a year. She had had periodical attacks of chills and high temperature, and at an interval of some weeks, sometimes a month, she would have a comparatively normal temperature, and be up and about—then she would have a repetition of the attack. Finally she fell into the hands of another man who made a diagnosis of an ovarian cyst and sent her for operation.

Dr. E. M. Sill has examined the urine of quite a number of babies with edema, and was unable to find albumin in any urine examined, except in those with very high fever, and in those cases he thought it was due more to the fever than any kidney inflammation.

Dr. M. Manges said the name edema, given by Dr. Baner, is a very apt one, and has its foundation in a very interesting theory as to the causation of dropsies and edema. Dr. Baner calls attention to the enormous importance of general nutrition, and especially as involving the permeable endothelium of the smaller vessels, and in giving the various etiological factors in the causation of edema and such conditions; he also lays especial stress upon the nutrition of the endothelial cells. It stands to reason that in these marasmic and underfed infants the endothelium will be much more permeable, and the name given by Dr. Baner of inanition edema might be accepted on that basis.

Dr. M. Manges presented a specimen of radium, a grain and a half in weight and described and demonstrated its action, although the case of cancer for which it had been purchased was not benefited by its use.

THE HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, held Saturday, October 24, 1903.

The President, Frank W. Daniels, M.D., in the Chair.

Appendicitis in its Diagnostic and Surgical Features.—This was the title of the paper of the evening and was read by Dr. John B. Walker, who said that every surgeon occasionally is surprised to find in cases of appendicitis where he expected that the operation would be comparatively easy that dense adhesions or other complications are present, making the operative procedures extremely difficult. It is evident in these cases that previous attacks of appendicitis have been completely latent, or have given such few symptoms as not to have attracted the patient's attention seriously, or a least not to have led him to call in a physician. These are the so-called recovered cases of appendicitis, yet it is evident that the recovery is a step toward the deterioration of tissue rather than any true improvement. These exceptional cases only serve to emphasize the difficulty of diagnosis, and of determining whether operation is necessary or not. The best authorities, like McBurney and Richardson, do not insist on operation in every case of appendicitis.

Simple Appendiceal Colic.—This affection is the simplest form of appendicitis and has for its principal symptom colicky pains. Usually there is disturbance of the pulse, but commonly no, or at most very slight, disturbance of the temperature. There is no true fever and no tumor can be felt. A few hours after the onset the pain diminishes and the patient usually goes on to satisfactory recovery. These cases are due probably to mechanical kinking of the appendix and are not truly inflammatory in character. If several such attacks occur it is evident that the appendix has become a point of less resistance and infection may follow with serious results, hence it is better to operate and remove that organ.

Suppurative Type.—In the second form of appendicitis, characterized by the development of suppuration, besides the pain there is a rise of temperature to 101° or 102° F. and of pulse to 120. The abdomen becomes rigid and tenderness over the appendix becomes marked. In these cases it is difficult to decide whether to operate or not during the attack. If suppuration should become extensive there is likely to be rupture of the appendix, followed by peritonitis with perhaps fatal termination. An important sign of advancing danger, in Dr. Walker's experience, has been the occurrence of pain when the abdomen is touched even on the other side. This extreme tenderness usually indicates that the collection of pus in the appendix has become tense and is in danger of rupturing.

Gangrenous Appendicitis.—In the third and severest form of appendicitis the preliminary symptom is usually severe pain followed by nausea and chilly feelings, often to the extent of a full chill and rigor. Sometimes there is a delusive amelioration of symptoms when gangrene sets in, during which the attending physician may

complacently consider that the patient is getting better. Most of the cases with sudden severe symptoms require early and immediate operation. It is not always easy to decide what must be done. Leucocytosis has been assumed to be of assistance in the diagnosis and the presence of a white blood cell count of 15,000 to 18,000 is usually a grave indication. Fortunately the largest number of appendicitis cases are not of this severe form but are simply catarrhal inflammations and amelioration can be looked for. In such cases the interval operation is the best and most suitable, besides being the procedure most likely to commend itself to the patient and to his friends, till they grow accustomed to the idea of operation. In some cases all signs fail and notwithstanding the fact that the classical symptoms of appendicitis appear to be present, at operation some other pathological condition is discovered. In the female, of course, ovarian disease may readily simulate appendicitis and must be constantly borne in mind. Even in true appendicitis the symptoms may vary from the classical type. At times the point of tenderness is not at McBurney's point, midway between the umbilicus and the anterior superior spine, but may be quite distant from it. In one case Dr. Walker even found it behind in the loin. A high leucocytosis is of value in helping diagnosis, but a medium leucocytosis gives no information except that any sudden increase may point to a serious progress in the pathological condition.

Premature Operations not Regretted.—As a practical conclusion it must not be forgotten that many surgeons have regretted delay in operating, but that there is no lasting regret over premature operation. For this reason then, the surgeon must be called early into the case to share the responsibility and must be ready to give the patient the benefit of the doubt by operating if there seems to be any good reason therefor. More than in any other disease, in appendicitis delay is dangerous. Even where recovery takes place the condition for future operation is always rendered a little worse. The unreasoning opposition to immediate operation in these cases is now gradually disappearing as the result of the growing conviction that early surgery is sure to be life-saving in the end and has very few objections. Dr. Walker's paper will appear in a subsequent issue of the Medical News.

Appendicitis and Pyosalpinx—Dr. Egbert Grandin said that pyosalpinx and appendicitis are symptomatically so closely related that mistakes are almost inevitable in many cases. In a recent case, he saw all the typical symptoms that are usually supposed to indicate appendicitis, the rigid rectus muscle, with knees drawn up, the pain in the right iliac region, with tenderness at McBurney's point and the general uneasiness so characteristic of intestinal trouble. As the temperature was low and only the pulse affected, the diagnosis of appendicitis seemed sure. The operation was done by an incision in the right iliac region and a normal appendix was found with right salpingitis and ovarian abscess. Six to eight ounces of pus were evacuated, yet the appendix lying in close contiguity with the abscess wall was absolutely normal.

Removal of Normal Appendix.—In cases such as those just described where the appendix is already in the operator's hands, Dr. Grandin prefers to remove the appendix, even though there are no pathological lesions in it. The removal of the appendix does not add to the danger of the operation while it is of distinct benefit to the patient in doing away with all risk of subsequent development of appendicitis. Even in cases where the operation is not on the right tube and ovary, but for some other gynecological conditions or intra-abdominal lesions quite distant from the appendix, he considers it better to remove this useless organ, which may so readily prove a source of subsequent danger requiring operation. Dr. Grandin has seen several conditions simulating appendicitis and does not always expect, even in apparently classical cases to find a diseased appendix. In one case recently he found a hernia of the ileum, through an aperture in the mesentery. Two inches of the gut had been forced through and the ileum was covered with a black fibrinoplastic exudate. A resection of the gut had to be done and afterward a careful search was made for the appendix, which was found to be perfectly normal. In a case of presumed relapsing appendicitis, in which there had been apparently several characteristic attacks, there were some anomalous symptoms, and consequently a doubt as to the pathological condition that might be found. A median incision was therefore made and the omentum was found adherent to the base and front of the bladder. This was tied off and after considerable search the appendix was found to be perfectly normal and was removed, to avoid subsequent complications.

Reflex Neuroses.—There seem to be a certain number of cases of appendicitis in which there is very little true inflammation. It is questionable whether these are neurotic in origin or whether they are of the so-called catarrhal type, a term which Dr. Grandin does not like. The main symptom of these cases is a low grade inflammation, which gives rise to so-called intestinal indigestion. At intervals the patient feels discomfort in the right iliac region, there is a sense of distention with constipation, though relief is usually afforded by a laxative. This used to be considered due to trouble around the cecum. Adhesive inflammation with narrowing of the bowel and disturbance of peristaltic motion. Such cases sometimes have a long history. Dr. Grandin has recently seen one that has run for eleven years and now has no further attacks. These are the cases that deceive physicians into thinking that they may have time to wait, though at any moment a fatal complication may be developing.

Interval Operation.—Dr. Grandin considers that it is better to operate in the interval, but there should be no waiting until tumor formation, though there seems to be an impression abroad, among general practitioners of medicine, that this should be looked for. If the patient has had one frank attack of appendicitis, there should be no question of waiting for another to decide the diagnosis, since a second attack may prove fatal. Certainly the old custom of waiting for a series of attacks, even though these are slight, is fraught with great danger for the patient and will often be a source of worry and annoyance to the attending physician and risk to the patient.

Indications for Operation.—The surgeon should not consider that the temperature is an important danger signal in appendicitis. Even though the temperature is normal, if the pulse be high the patient should be operated upon. Any sudden change, especially in the patient's sense of discomfort, should be the signal for serious consideration as to the necessity for operation. In gangrenous cases it must not be forgotten that the patient may become quite comfortable, just at the moment when operation has become absolutely necessary if life is to be saved.

Elective Appendicectomy.—Dr. Grandin believes that whenever the abdomen is opened for any other condition, the appendix should be removed whether it shows signs of disease or not. This puts the patient at once beyond all the dangers likely to accrue to him from the possession of this useless organ. It takes but a few minutes to do the operation, it adds nothing at all to the risk to anyone who understands the circumstances;

certainly any physician or surgeon himself, would prefer to have his appendix removed under such conditions, instead of leaving it to the chance of fate and future danger.

Unwise Waiting.—Dr. William B. Coley said that many a physician has learned the unwisdom of waiting to have the operation for the removal of the appendix done on his patient in the interval. No set of symptoms can be depended on to give absolute information as to the time when operation should be done. In a recent case Dr. Coley operated upon a patient with a normal pulse and temperature. In this case there had been some gastric symptoms but no local pain or tenderness, and there was only a generalized colicky pain which increased in amount. The pulse was at 73, the temperature 98.5° F. Great rigidity and pain developed over the lower part of the abdomen and this was so marked that it was considered necessary to operate, although the operation was done within twenty-four hours after the development of the first symptom, the whole pelvis was found full of pus. In a case in Brooklyn not long ago the patient developed a temperature of 103° F., which gradually subsided in the course of the two subsequent days to normal. Suddenly collapse took place and death followed, and as no autopsy was allowed, the absolute condition present could not be determined.

Danger of Waiting.—It is good principle to wait, but it is fraught with danger. Dr. Coley visits a summering place every year and finds that country practitioners wait even more than their city brethren, and as a consequence there are some gaps in the circle of acquaintances every year with the story of death from appendicitis. It is not often that a surgeon regrets having operated too soon. Physicians and surgeons both often regret having waited too long.

Differential Leucocyte Count.—Dr. George Brewer said that there has been serious disappointment because of the failure of the leucocyte count to give any definite information with regard to the development of a septic process. At one time it was thought that this would be of significant value. Very recently he has found that the differential leucocyte count seems to give important information. It is possible to have a low leucocytosis, yet a septic process be in full swing. A differential count will show in these cases according to the experience at Roosevelt Hospital, that the polynuclear leucocytes are increased much more than their due proportion. Usually the polynuclears number about 62 per cent. of all the leucocytes. When over 70 per cent. of polynuclear leucocytes are present the surgeon may look for abundant pus formation. In several recent cases in which this was true very large abscesses were found.

Failure of Leucocytosis.—Dr. Fiske said that it is evident that in appendicitis as in pneumonia leucocytosis may fail to make its appearance in certain cases. In pneumonia experience shows that the absence of leucocytosis speaks for special virulence of the disease. The same thing would seem to be true with regard to appendicitis in certain cases. To look for leucocytosis then may be worse than useless. Dr. Fiske believes that time can be saved by operating early. If the patient comes down with appendicitis and is operated on at once, he will be able to be around in three weeks, or less as a rule. If after the attack is over, ten days or two weeks are consumed in waiting until the patient is supposed to be ready for operation, altogether at least six weeks will be required before the patient can be out of bed. Early operation has no regrets.

Dr. Howard Lilienthal said that it requires much more courage to advise waiting than to counsel operation. No surgeon or physician, no matter what his experience, can tell absolutely, so treacherous is appendicitis, what will happen in the next hour in a given case. The case may be running an apparently normal course and yet the virulence of the infection may be such as to cause septic thrombosis of the mesenteric veins. If this happens then the removal of the appendix will not be followed by recovery but the patient will develop further septic conditions, liver abscess may occur and death will take place in two or three weeks. This constitutes an important argument for early operation and against not waiting.

Mount Sinai Experience.—Last year at Mt. Sinai 110 cases were operated upon for appendicitis. There were about 8 per cent. of deaths—all cases being included in the statistics, even those that were considered to be suffering from general peritonitis at the time the operation was performed and who were operated upon only to give them a possible chance for life. The older statistics gave between 20 to 25 per cent. of deaths in these same cases. Dr. Lilienthal gave some details of typical cases in which delay was made because of the influence of other consultants and in which, even when the issue was not fatal, the patient was not benefited by the delay. In a recent case the abdomen was extremely sensitive so that the patient could only be examined under an anesthetic and there were the signs of general peritonitis. Turbid fluid was found in the hypochondrium and in the pelvis. As little packing as possible was used in the case, so as to avoid injuring the peritoneum. Even the use of gauze pads in these cases almost surely does harm. A small cigarette drain was inserted down to the root of the appendix and though the case seemed hopeless the patient recovered. In such cases death was inevitable a few years ago and now many of the patients are saved. Dr. Lilienthal has found the blood count absolutely of no use and considers that when there is doubt the best thing to do is to operate.

True Appendicitis.—Dr. Lilienthal gave the details of certain peculiar symptoms occurring in his own daughter, aged nine years. She suffered from a peculiar stomachache of colicky nature, during which, however, there was no fever, no rise of pulse, no localization of symptoms and no tenderness of the abdomen. It recurred several times at long intervals and then began to recur at shorter intervals. It was causing so much discomfort that operation was decided upon, and as a sensitive point in the right iliac region could be found on deep palpation, the incision was made as for an ordinary appendicitis operation. Much to Dr. Lilienthal's surprise two fecal concretions were found in the appendix and with them some grape-seeds. The mother of the child had always insisted that it must not swallow grape-seeds. The Doctor himself, doubting that grape-seeds had ever caused any appendicitis, had rather winked at the idea of such a stern prohibition and now realizes better the good advice it was.

Appendicitis and Diagnosis of Peritonitis.—Dr. Frank Daniels said that appendicitis itself is not diagnosed until it causes an accompanying peritonitis. The true diagnosis of appendicitis cannot be made because, while that organ itself is alone affected, it does not give sufficiently pathognomonic symptoms. In a recent case under Dr. Daniel's care he had a somewhat similar experience to that of Dr. Lilienthal. The patient suffered from attacks of colicky pain, but without any definite localization and without any rise of temperature or increase in the frequency of the pulse. He has become convinced himself that such mild, obscure cases of appendicitis, are much more frequent than has been thought and constitute preliminary symptoms usually so little attended to by patients that they tell their physicians nothing of them when more serious conditions develop. It is sometimes the custom to speak of these as functional or neurotic, but they are probably organic.
